As to the clinical value of digitalis itself, I have long since given it up, for a number of reasons. Its action is not constant. You have to wait a long time before you see any action, and when you do see it, the action may be too powerful, so that instead of getting, say, one hundred pulsations a minute, as you desired, you may get forty, with perhaps vomiting and the other symptoms of poisoning. This accumulation of its effect is very frequent. Again, when given in infusion, digitalis is very apt to have a primarily irritant effect upon the mucous membrane of the stomach. For these reasons I have abandoned the use of the drug in this form, and use only the "*digitaline*," the so-called alkaloid, though it is not an alkaloid. This has the preference over digitalis that its action is uniform and not cumulative, so that you can give it for a considerable time and readily watch its effect. If you give one-sixth of a grain a day, you are tolerably sure that the effect of the second or the third sixth will not be much more powerful than was that of the first. I have never seen an unfavorable symptom follow the exhibition of digitaline, although I use it in much larger doses than those laid down in the books. These give one-twentieth to one-twelfth of a grain per day as the febrifuge dose for an adult. I have said that children require proportionately larger doses of antifebriles than adults; a child of four years will demand not one-fourth the adult dose, but even one-half, and now and then the full dose. I have thus given digitaline in pneumonia—not less than one-fourth of a grain the first day, often one-third of a grain, and not rarely one-half, and even more, when I was sure I could see the child again within twelve or sixteen hours. Digitaline may be administered either in pill or in a liquid, although it does not dissolve very readily. In chronic pneumonia, chronic endocarditis, chronic inflammation of the valves of the heart, I am so sure of the effect of this drug that I give it to office-patients and continue it for weeks. I send them off with prescriptions containing perhaps one-eighth of a grain per diem. To children, in chronic inflammations, I would give about half the dose proper for an adult; to a child of three or four years, suffering from chronic defect of the cardiac valves, I should hardly dare to give less than one-twelfth or one-sixteenth of a grain daily. It may be said of this, as well as of veratrum, that, while it reduces the frequency of the heart-beats, it certainly increases their power. These remedies are, therefore, not contra-indicated, but are indicated, in inflammatory diseases, and, by augmenting the power of the circulation, they tend to prevent congestion or stasis, of which there is so much danger, for example, in pneumonia.

Of the preparations of veratrum viride, I prefer Nor-

wood's or Percy's tincture to any other. In the acute pneumonia of a baby I give a drop of the tincture every hour; to a child four or five years old, perhaps two drops every hour. If the attendant is intelligent enough to count the pulse, I say, Bring down this pulse to one hundred and ten or one hundred, but not lower; because when the pulse falls lower the drug is apt to cause vomiting and temporary collapse. To obviate local irritation of the pharyngeal or gastric mucous membranes I give the tincture in barley water. This drug has no cumulative effect like that of digitalis. It will bear combination with quinine, and I think this is an important point. I often combine quinine with veratrum or digitalis where I want to get not a speedy but a continued effect upon the pulse. Especially in the pneumonia of a debilitated child, where you are in doubt about stimulating to any great extent—where you do not know whether you ought to commence with benzoic acid, camphor, etc.—you will control the pulse better with quinine and veratrum than with the latter alone. I ought to add that in most cases it is advisable to combine opium or hyoscyamus with veratrum, to obviate local gastric irritation.

CAMPHOR.

I have mentioned camphor. I account this an antiphlogistic, and I use it much, especially in pulmonary inflammations where a stimulant expectorant is needed; in all cases where I require a stimulant to avert the danger of collapse; and in all cases of secondary inflammation of the lungs, no matter whether due to a previous pneumonia, or to whooping-cough, or some other cause. I give camphor certainly as soon as hepatization is established, which is generally within twenty-four hours or less. Camphor is a physiological antiphlogistic, reducing the pulse and temperature even in the healthy person; and, like alcohol, it has the same effect in patients suffering from an inflammatory fever like that of pneumonia. In secondary pneumonia, especially, you will find it do more than any other expectorant; or, at all events, its effect is more protracted. One of the pet excitants in such cases is carbonate of ammonia; but while we confess that its effect is speedy and powerful, we must recognize, at the same time, that this effect passes off just as rapidly as it has come on.

OPIUM,

it is well known, is an antiphlogistic in a number of inflammatory diseases; there is none better, for instance, in enteritis, peritonitis, etc. But I believe that as an antiphlogistic in most of the inflammatory diseases of infancy and childhood it should be avoided. The doctrines of its effect upon the circulation do not seem to be so well established that we can fully rely upon them; but I think the old theory, that it dilates the blood-vessels, deserves more confidence than do the few later experiments which appear to show that it contracts them. If this be so, then opium would be contra-indicated in the fevers and inflammations of early life, because we know that these are then especially dangerous from their tendency to affect the brain. We know that, in an infant, convulsions or other brain symptoms will speedily follow even a very mild fever. This is due to the facility with which the blood-vessels of the brain dilate, at a period when the head is still growing, when the sutures are still loose, and the fontanelles still open. Any remedy tending to dilate these vessels then becomes dangerous. Thus while I am in the habit of using opium to a great extent in other affections of infancy and childhood, I refrain from its use in inflammatory and febrile affections, excepting in peritonitis, or perhaps to relieve irritation or cough, momentarily, in diseases of the respiratory organs.

QUININE.

I have a few remarks to make upon that all-powerful febrifuge, quinine. It has a number of advantages. First, it is thrown off from the system in the same condition in which it was introduced; it is not decomposed, but is eliminated as quinine. (We must say the same of alcohol when it is given only to a limited extent, though when large amounts are taken a part of it suffers decomposition.) Another advantage which, in my opinion, quinine has over other febrifuges, is that it is absolutely innocent. It is true that when large doses are given, some immediate, but transient, unpleasant effects will now and then follow. There may be buzzing in the ears, with perhaps temporary deafness; and even temporary blindness has been observed. A number of cases of permanent deafness have been reported as dependent on the use of the drug; but, after a careful scrutiny, it appears that there is not one of them which cannot be explained in some other way. In my opinion, there is not a single well established case, where permanent deafness has followed the use of large doses of quinine. Quinine was first introduced as cinchona. This is very good, but large doses are not well tolerated by the stomach, which soon exhibits symptoms of catarrh.

The credit of first employing quinine as a febrifuge is due to Broussais, who made his experiments in 1852. The effect of quinine upon the enlarged spleen was already well known. When you subject a spleen, that has been suddenly enlarged by intermittent or typhoid fever, to the influence of a large dose of quinine, you are positive that within five or six hours you will be able to demonstrate by percussion a diminution in size. This has been proved, as well, by experiments on animals. Kückenmeister, about nine years ago, showed that the normal spleen would contract in starving animals. He attributed this to the contraction of its blood-vessels, and of its proper muscular fibres. It was some time after these experiments before quinine was practically tried in the inflammatory diseases of infancy and childhood. The first diseases in which it was tested on a large scale were typhoid fever, etc.

Quinine, then, would appear to cause contraction of the blood-vessels, with contraction of the unstriped muscles generally, and especially of those not influenced by the pneumogastric nerve. It would seem also to have a further effect upon the brain, by which reflex action is greatly diminished, if not abolished. This is shown not only by clinical observation, but also by direct physiological experiments. Its effect of diminishing reflex irritability explains the action of quinine in curing or preventing reflex convulsions, especially those apt to return frequently. This effect, however, requires a tolerably or at least partially intact condition of the nervous centre; for when destruction of the lower part of the brain, near the medulla oblongata, has taken place, the effect of the quinine is seen no longer.

Another very valuable property of quinine is its antifermentative action. Given internally, or applied locally, it has been found to act favorably in necrosis, cancrum oris, etc., as well as in all those diseases supposed to depend upon the presence of fungi in the blood. Although Salisbury in America, and Hallier in Germany, may perhaps have gone a little too far in their views of the parasitic origin of disease, still it is pretty well established that many diseases must be attributed to parasites in the blood, and not to noxious gases. In such cases quinine, since it is discharged

from the body unchanged, seems to act by catalysis in preventing fermentation. There is no more powerful febrifuge in these so-called zymotic diseases, especially in scarlatina, measles, and, it is said, whooping-cough. My own experience with it, in this last affection, is not sufficient to enable me to speak satisfactorily. But whooping-cough has been considered to belong to the same class of diseases, spore-like bodies being, it is said, found in the sputa. It is a fact that when quinine is brought in contact with the tough, hard sputum in the larynx and pharynx, the attacks of coughing become less frequent; but beyond this I cannot speak from experience. In all diseases, then, where there is a tendency to septicæmia or cholæmia, quinine is the chief remedy indicated.

A further effect of quinine is to destroy, or paralyze the action of, the white blood-corpuscles. In all cases where it has been given in large doses, the number of these corpuscles is found to be diminished; in leucocythemia, for example, after large doses of quinine, the relative proportion of the red and white corpuscles becomes less abnormal. I use it a great deal in those cases where there is to be feared a migration of white corpuscles; for instance, in the very frequent cases of chronic pneumonia which, when they have lasted a long time, threaten, as their chief source of danger, besides infiltration of the pulmonary tissue, the formation of abscesses resulting from such migration. Especially when, in such cases of chronic pneumonia, or chronic bronchopneumonia, there is a little afternoon fever, a slight rise of temperature about four or five o'clock, quinine is the only thing we can rely upon. I give a child four or five years old some half-dozen grains, either in the morning or just before the fever is expected to set in. Children will take this dose for, say, ten days; and as long as they have need of it they will not complain of any unpleasant effect; but as soon as it becomes superfluous, as soon as the afternoon fever has ceased, they will begin to complain. Recently I gave this amount to the child of a friend of mine for six days. On the seventh day there was no afternoon fever, and the little girl said, "Papa, I have music in my ears."

The doses of quinine generally given are, I believe, decidedly too small—indeed, I know that they are. If the drug is to have an antifebrile effect, it must be given so as to reduce the pulse and especially the temperature; nothing which fails to do this can claim the name of febrifuge. Now I have often found that, in the pneumonia of a child of two years, a dose of five or six grains would have no such effect—none at all upon the temperature and hardly any upon the pulse—while a dose of ten grains would diminish both. I have made ever so many measurements of temperature in the rectum—the only place reliable—to satisfy myself upon this point; and when one has tested it satisfactorily, he will certainly in his next case give the ten grains at first, and not waste time on the smaller doses because the books prescribe them. At the present day we have the advantage of the thermometer in determining the action of remedies, and we have certainly as good a right to fix their doses as had those less fully armed twenty or thirty years ago.

I deem quinine indicated, also, in all secondary inflammations. In such a case I would not give less than five grains to any child of any age. With this dose I have frequently obtained a good effect in very young infants; but a child of one year will often refuse to respond to the remedy until seven or eight grains are reached; and to a child of seven or eight years I seldom give less than ten grains. The dose need not be frequently repeated. If you can see the patient in the morning and give him one good dose, you will probably find, in a few hours, that pulse and temperature have both notably fallen, or at all events not risen, as you expected. It is a curious fact that by quinine the temperature is first reduced, and the pulse follows; while by veratrum, digitalis, and remedies of that class, the pulse is the first to be affected. Therefore, as the temperature is the main element in fever, quinine would seem to be the febrifuge proper.

How shall we administer quinine? It is most surely and speedily introduced into the system when given in solution. The sulphate requires about eight hundred parts of water to dissolve it, the chloride (muriate) only about thirty parts. The latter is, besides, more kindred to the fluids of the stomach. When an acid is to be given, I prefer hydrochloric to sulphuric. Therefore, except when its price interferes, I generally prescribe the chloride of quinine, as more readily soluble in the gastric juice.

The sugar-coated pills I think it dangerous to trust, because in many instances the drug will not be absorbed at all, since the pills will not be dissolved. I have, a number of times, seen sugar-coated pills of quinine, iron, etc., discharged in the evacuations; and I am not the first to observe it, my attention having been directed to the fact by professional brethren in this city. I think it is of very frequent occurrence, especially where there is gastric catarrh.

A preparation of quinine, which has been resorted to on account of the disagreeable taste of the other salts, is the tannate. This, which is given in doses about double those of the sulphate or chloride, is nearly insoluble; and I believe many a dose has been poured down and never dissolved at all. Where I wished both to conceal the bitterness of the quinine and to get the local effect of the tannic acid, I have given the two together in the form of powder. Where we do not desire the local action of the tannin, the addition of one-fourth of a grain of this to two grains of quinine is sufficient to cover the taste to a great extent.

A mode of administration which I should prefer is, I fear, a little dangerous as yet—that of subcutaneous injection. The muriate is the only salt we can use for this purpose, and even this it is very difficult to dissolve with a small enough quantity of acid not to make the solution irritant. In an article by Prof. Binz, of Bonn, which will appear in a few days,* is described an amorphous muriate of quinine, soluble in its own weight of water, upon which I intend to experiment. It would certainly be an immense advantage in many cases if we could conveniently exhibit quinine by hypodermic injection, so as to obtain suddenly the effect of a powerful dose. I have, for some time past, used a saturated solution of chloride of quinine, which became liquid at 100° Fah., but was solid at a lower temperature. In a case where I used this preparation a number of times, I had an opportunity to make a post-mortem examination after a few days. I found large deposits of unaltered chloride of quinia in the adipose tissue

Injection into the rectum is in general just as effective as administration by the mouth. Not so much can be said, however, of the inunction of quinine, although a French writer, Semanas, has put forth a large book upon it. I have had recourse to it sometimes when both stomach and rectum would refuse to accept the remedy. And I am sure that I have been benefited by the plan of embrocations of solutions in glycerine. The dose I have been using has been four times that used internally.

If the doses I have been advocating to-night appear

* *See Am. Journ. Obstetrics*, May, 1870.—REP.

too large, I would simply desire the gentlemen to make their own experiments, but with thermometer in hand. Before the employment of this test, Guérin had insisted that quinine was much better tolerated by children than by adults. This has been my own experience, and we are able to demonstrate its correctness by the aid of the thermometer. I shall be thankful to those gentlemen who will illustrate the matter by further experiments.

THROMBUS OF THE VULVA:

A CLINICAL LECTURE, DELIVERED AT BELLEVUE HOSPITAL,

By FORDYCE BARKER, M.D.,

PROFESSOR OF CLINICAL MIDWIFERY AND DISEASES OF WOMEN, BELLEVUE HOSPITAL MEDICAL COLLEGE.

[Phonographically reported for THE RECORD.]

GENTLEMEN:—A long time ago, at the very commencement of my practice, I was called to attend a young woman in labor. Everything seemed to be progressing favorably, when suddenly the patient screamed, threw herself to the other side of the bed, and appeared to lose all self-control. A few minutes before this I had made an examination, and found the cervix dilated and the head descended into the pelvic cavity. I was promising myself a speedy termination of the labor, till startled by the interruption of it just described.

The patient was suffering such intense pain, and the parts were so tender, that it was some little time before I could get another examination. Then I, at first, discovered a tumor, of a hardness resembling that of the fœtal head; and I thought the fœtus was just escaping from the vulva, and that it was the agony attending this which had brought the patient to her distressing condition. But I soon found that she was losing a good deal of blood, and that the uterine contractions had ceased. Her excitement and anxiety I was able to calm by perfect self-possession; but I was unable to make a satisfactory diagnosis. The indication was evidently to prevent loss of blood, though as to what the hæmorrhage meant I had not the least idea. To fulfil this indication I applied a saturated solution of alum, and made a pretty strong pressure upon the tumor, which I kept up for an hour or two, the labor-pains all the while being stopped.

The case being so obscure, I decided to call a consultation. A physician much older than myself was sent for, who made a comparatively hasty examination, and at once pronounced the case one of placenta prævia; saying that he had often had such cases; that, owing to the severe pain produced by my application of alum and compression, I had arrested the labor, and it might be some hours before the pains returned, when he would be sent for again. On the whole, he damned me with faint praise; thought I had done very well, considering that I was a very young man, just beginning practice; and, as I afterwards learned, censured me, to the family, for the ridiculous folly I had been guilty of in making my applications. He left, with directions to be called when the labor recommenced. I was hurt and humiliated, but not convinced. I found, too, that the consulting physician had not favorably impressed the family, while I had rather won their confidence and sympathy.

In the mean time my measures had stopped the hæmorrhage. About an hour later, it returned to a considerable amount; and, as the patient's chief danger seemed to be from loss of blood, I saw nothing better than to renew them. They could certainly do no harm. In applying the compresses I embraced the opportunity to make examinations, and presently came to the conclusion that there must have been some solution of continuity in one of the labia, to account for the bleeding. The nurse was a sensible woman; and, directing her to keep on the alum and compresses, I went home to consult my books. Though my library was tolerably rich in works on obstetrics, I could find nothing, as I hastily turned them over, except a short description of extravasation into the labium, with no directions for treatment. I reflected that it would not do for me, a young, unmarried man, with a reputation to make or to mar, to let the woman die with a child in her. So I turned over my books again for directions as to the use of the forceps, took my forceps, and went back to the house.

During my short absence the tumor had so increased in size that it was with difficulty I could pass my fingers into the vulva, especially since it caused the patient so much suffering—for this was long before the days of anæsthetics. The head was pretty low down, but the woman had lost still more blood. I said to myself: With this bleeding and this tumor there is no chance of the labor's terminating spontaneously; or, if there be such a possibility, and I wait for it, there must at least be a great loss of blood; the patient will probably die, and that will be ruin to me. I applied the forceps and delivered a living child. This was my first forceps case. Immediately following delivery there was a tremendous gush of blood, and almost as soon as the blood had escaped the tumor filled up again. With no authorities and no experience to guide me, I could only follow a sort of instinct, with the conviction that it was leading me right, or, perhaps, a non-formulated logic which it would have been difficult for me to defend. I am sure, gentlemen, that no general in time of battle, considering that he held the fate of an army or a nation in his hands, ever felt a heavier weight of responsibility than I did here; and, although this was twenty-eight years ago, every incident and detail of the case is stamped indelibly on my memory, as vividly as if it had occurred but yesterday. From further examination I satisfied myself that laceration of the labium had taken place, and that the extravasation of blood was into this. I recollected that Hunter, in his work "On the Blood" (which I had studied carefully in my early pupilage, and which still remains a great favorite with me), had described the case of a woman who had accidentally fallen upon the handle of a water-pail, causing laceration of the labium with great hæmorrhage. Hunter had left the coagulum to compress the lacerated vessels and stop the bleeding; had then poulticed the part and bled the patient, to keep the tissues soft and relieve pain. Suppuration had taken place, with discharge of clots, and eventual recovery with a slough. This case had not occurred in pregnancy, but it was my only guide, and I followed the plan of treatment there indicated. It was some time before my patient recovered. She had a gangrenous slough, by which the whole labium was completely destroyed. The woman got well, however, though with only one labium, and the child also lived.

Now, gentlemen, if you look through all the text-books on midwifery in the English language, including the translations into English, you will not find in one of them plain directions for the management of such a complication of labor as this. To be sure, thrombus of the vulva is now described in several books, though not in text-books on obstetrics, with the exception of Cazeaux, as a complication of labor. Very shortly after this first case of mine, I found in "Dewees on Diseases of Females"—not his work on midwifery—a very clear description of this class of accidents. Meigs

also, in his "Familiar Letters on Diseases of Women," gives a pretty clear description of it, and also McClintock on "Diseases of Women." There is a short account in "Simpson on Diseases of Women," and another in Burns. Cazeaux has the clearest and best-written article on the subject, extending to several pages, and giving excellent instructions for treatment where the accident occurs previous to labor. Bedford, in his "Obstetrics," gives a very fair description of this complication, but the directions for treatment are vague. The periodical literature of medicine does not lack reports of such cases, and in a French monograph by Deneux, published in 1830, there are sixty-two reported cases of thrombus of the labium, occurring before, during, and after labor; and out of this number twenty-two of the women died, and twenty-one of the children were lost.

I need make no apology, then, for endeavoring in some measure to supply the deficiencies of your text-books upon this subject, by bringing before you to-day a case which occurred in this hospital a week ago last Sunday. The patient is now being brought in, and the House-Surgeon, Dr. ALEXANDER C. GRAHAM, will read you his report of the case.

Margaret ———, æt. 19, New York, primipara. Labor-pains began about 12 o'clock the night of January 15th, and continued with only slight intensity all the next day. At 5 P.M. (Jan. 16th) the bag of waters broke, and the patient was immediately sent to the lying-in ward.

On examination no deformity of the pelvis or of the soft parts was found; the cervix was soft, moist, and dilatable, the os being an inch and a half in diameter. The vertex was presenting in the left occipito-anterior position. Fœtal heart heard on the left side below the umbilicus, 130 per minute. At 7.30 P.M. the cervix was fully dilated, and the uterine pains continued good and regular. In a short time the head descended to the inferior strait, and remained there till 11.10 P.M. The woman seemed to suffer a good deal of pain and could not be made to bear down.

While making an examination at this time, I noticed that the right labium majus was more swollen than at the previous examination, and that it was rapidly enlarging. I supposed immediately that I had to deal with a thrombus of the vulva, and endeavored, by moderate and equable pressure, and the application of ice, to prevent its increase. The patient says she never noticed any tumor about the vulva during pregnancy, nor received any injury in that situation.

In twenty minutes the thrombus was as large as the fist, its mucous surface being purple; and the patient was suffering intensely. The labor-pains now ceased—the head being at the inferior strait, not yet having distended the perinæum. While making preparations to incise the tumor, its coverings broke, and profuse hæmorrhage of an arterial character followed. The opening at the border of the mucous membrane was enlarged by incision; the clots turned out: and the cavity, three inches in depth, filled with a piece of ice. The head was not far enough down to make compression, and efforts to make the labor advance were unavailing. The hæmorrhage still continuing, the cavity was tamponed with pieces of sponge soaked in the liquor ferri persulphatis; this, along with firm compression made by the hand, arrested the hæmorrhage.

An ounce of urine was now drawn from the bladder, and the fœtal heart was found to be pulsating on auscultation. Dr. Barker was sent for, and, at twenty minutes after 12 o'clock, the patient being under chloroform, applied the short forceps. The child, weighing 7¼lbs., was born at half after twelve. The placenta came away in a few minutes. The hæmorrhage was now frightful—a perfect stream of blood of a bright red color falling into the vessel at the foot of the bed. The opening was again enlarged by incision, and the cavity of the thrombus tightly plugged with pieces of cotton soaked in liq. ferri persulphatis.

The bleeding now ceased; but the pulse had become imperceptible and the face was intensely pale. Two drachms of U. S. sol. morphiæ sulphatis in an ounce of whiskey were immediately given and repeated in half an hour. After the first dose the pulse was 165, very small and weak. At 3.30 A.M. it was 120 and fuller. As much beef-tea as patient would take was given, and she soon fell asleep.

At 10 A.M., Jan. 17th, there had been no return of the hæmorrhage. The vulva was gently washed with warm water containing liq. sodæ chlorinatæ, great care being taken not to disturb the large clot. The urine was drawn off, and the parts were covered with a piece of lint soaked in carbolic acid and glycerine (1 to 20). The vagina is to be thoroughly syringed, several times daily, with water containing the liq. sodæ chlorinat. Ordered two grains of quinine and one-half grain of opium every six hours; stimulants and a nutritious diet.

Jan. 18th, 10 A.M., pulse 92; respiration 18; temperature 100°. The same treatment is continued. There is no sloughing about the wound. While washing the vulva, part of the clot comes away, but there is no bleeding. At 7 P.M. pulse 120; respiration 21. This afternoon a poultice was applied to the vulva, and to-night patient passed her water. Her bowels are confined; the lochia are free.

Jan. 26th. The patient has steadily improved, without an unfavorable symptom. Her bowels were moved, several days after her confinement, with a laxative. The wound has cleaned off and is granulating nicely. Ordered iron and quinine.

You observe that we kept everything scrupulously clean by a wash of chlorinated soda. By the use of the catheter, and by having the parts covered with glycerine and carbolic acid, all excoriation or irritation from the passage of urine was prevented. The tumor has now almost entirely subsided, with but slight suppuration and no sloughing whatever. The patient has got along wonderfully well, and both she and myself are greatly indebted to the excellent judgment and care of Dr. Graham, who has had charge of the case. Willing to be made the means of saving others from the dangers by which she was threatened, the patient has consented to be exhibited. You see how healthy the tissues are looking, and that the parts are almost of their natural size, though the tumor was as large as my fist. The woman has been placed upon the most nourishing diet. She has made no fuss through the whole, and has been altogether a most excellent patient. Now she can be taken out and given a little whiskey.

This accident is one which may occur at any period of gestation; it may be found as a complication during labor; or it may not become manifest until after the labor is terminated. As I have said, it may occur during gestation, *before* labor, and I have met with several such cases, and also with a larger number, *after* labor; but the case just shown you and that which I first described are the only two which I have seen where it occurred *during* labor, although, as we have seen, the literature of the subject records many such cases. I have recently learned, too, that my colleague, Professor Wood, has had one case as a complication of labor, and that Professor Sayre has had two—all very distinctly marked. There are quite numerous cases reported occurring subsequent to labor; but then the accident is far less dangerous, and its fatality comparatively slight. Cazeaux's directions for the management of those cases belonging to the time of gestation are full and most excellent. I shall confine myself, therefore, to the diagnosis and treatment of the accident where it complicates labor.

Thrombus of the labium, or labial hæmatocele, has been mistaken for labial hernia, for inversion of the uterus, for thrombus of the bladder, for thrombus of the vagina, for the fœtal head, for placenta prævia. Thus you see that in very many cases it has escaped diag-

nosis. It seems to me that, in all these cases, the mistake must have arisen from ignorance that such an accident was liable to occur. For if aware of this liability, a physician could hardly mistake the tumor for hernia or abscess, especially when taking into account its sudden development at the time of labor. The sudden and intense pain, the sudden and profound disturbance of the nervous system, the profuse and dangerous hæmorrhage, which occur—these, in connection with a careful physical examination, which at the present day you can make with the patient completely anæsthetized, seem to me sufficient to establish the diagnosis easily.

Making an examination while the extravasated blood has simply infiltrated the cellular tissue and not yet lacerated it, you find the tumor hard and feeling very much like the fœtal head covered with the tumefied scalp. After laceration of the cellular tissue you get the sensation of fluctuation, and then the tumor could not be mistaken for the fœtal head.

The character of the hæmorrhage which occurs, and its want of coincidence with the uterine pains, should protect you from mistaking the case for one of placenta prævia. The sac may be ruptured, and the effusion of blood take place, either high up in the cavity of the vagina, or near the junction of the mucous membrane with the skin. In a case reported, it was found that the fœtal head rested against the walls of the sac, so that whenever uterine contractions came on, the pressure of the head arrested the flow of blood, and there was instead a gush of liquor amnii. This, of course, made it plain that the hæmorrhage was not from the cavity of the uterus. In another case the rupture took place very high up; there was escape of blood into the cavity of the peritonæum; and the patient died from this hæmorrhage into the abdomen, the external discharge being very slight.

There is always intense pain until laceration of the cellular tissue takes place; after this the pain is less severe, because the parts more readily yield before the pressure to which they are subjected.

The moment the head has escaped, there is of course an excessive flow of blood. In one of Professor Sayre's cases a clot was at this time projected with great force, passing over the head of Professor Elliot, who was present.

Where extravasation takes place during labor the danger is very much increased, notwithstanding that Velpeau says there are then no vessels in these parts of sufficient size to occasion danger from loss of blood. It is the fact that in some of these cases the amount of blood lost is very great, so as to produce death from this cause alone. In the cases apparently occurring immediately after delivery there is no doubt that the rupture of the vessels has been produced during the labor, although the extravasation has been delayed by the pressure of the head. In the second case reported by Professor Sayre the labor had terminated without loss of blood—in fact it was a remarkably dry labor. The child and the placenta had been delivered, and the patient had been watched for some little time, when there were symptoms of a recurrence of labor—strong bearing-down pains, which led my friend, who describes the case in his usual dramatic manner, to make an immediate examination. There was a tumor in the labium, feeling at first so much like a child's head that for a moment he feared he had made a blunder, and there was another baby to come. But palpation of the abdomen showed the uterus contracted. This case well illustrates the point that the tumor is at first exceedingly tense and hard.

There are one or two points to which I would call your attention, on which my experience is opposed to the statements of the writers upon this subject. First, it is asserted that the accident is almost always a consequence of varicose veins. Now, in neither of my two cases, in neither of Professor Sayre's, nor yet in Professor Wood's, were there any varicose veins at all. And I can say the same of the cases I have seen in which the thrombus appeared previous to labor. In the case just shown you it was evident that the blood came from a ruptured artery, for it was distinctly arterial.

Another point: Cazeaux states, and so do other authors, that the rupture occurs just as the head, or the presenting part, is escaping from the vulva. This was not the fact in my cases. The head was in the pelvic cavity, pretty well down towards the perinæum, but not yet in the least distending either this or the vulva. It was the same in Professor Sayre's cases.

I come now to the management of this accident when it occurs as a complication of labor; for, as I have said, the authors referred to give you ample directions for its management when occurring in gestation. The better to enforce the various points, we will take the case just now before us as a type.

As soon as Dr. Graham recognized the large tumor, he made an incision and turned out the clots. There had been extensive laceration before the incision. One of the staff asked me whether it was not a mistake to incise at so early a period; whether it would not have been better to wait until just before the application of the forceps. Now let me recommend to you, gentlemen, as a habit of life, always to review your cases, be their termination favorable or unfavorable, and ask yourselves if the treatment might not have been improved. I was glad to hear the question I have mentioned, for it showed this habit; and now I will answer it. I think the early incision was not a mistake, but was the very best treatment; because, the longer incision was postponed, the greater would be the amount of extravasation, the greater the distension of the parts, the more extensive the laceration of their areolar tissue. The argument of Hunter, that the clot would act as a compress, a tampon, to arrest the hæmorrhage, is, I think, altogether erroneous. In my own case, where I followed his plan, there was extensive sloughing, and the whole labium was lost. In this last case nothing of the kind has occurred; and so it was in both of Professor Sayre's. Incise at once, then, so as to relieve the parts from the pressure, and relieve the patient from the shock of the severe pain attending the tearing of the tissues—a shock far greater even than that of ordinary labor-pains. We can arrest the hæmorrhage promptly and surely by applying directly to the bleeding surface the powerful styptic, persulphate of iron. Turn out the clots, find the exact point of laceration, and apply this styptic.

The next question was between speedy delivery by artificial means, and waiting till the system should recover from the shock, and trusting nature to deliver the woman. I decided to deliver as quickly as possible with safety to the patient, and for this reason: I have already shown you that the accident is not due to varicose veins; but the exciting cause is arrest of the venous circulation by the mechanical pressure of the presenting part of the fœtus. If this be so, the sooner the pressure is removed, the sooner will the danger be over, and the less will be the injury to the parts. Deliver as soon and as rapidly as possible, and be prepared to meet the great gush of blood, that you must expect as soon as this is accomplished, by the means adopted in the present case. Apply compresses of cotton batting, saturated with solution of persulphate

of iron, directly to the bleeding part, and keep up pressure till the hæmorrhage stops. This patient was reduced almost to the last extremity by loss of blood; but these measures arrested the hæmorrhage, and whiskey and morphia brought back the pulse, which had become imperceptible.

Every author, I believe, directs that a tampon be applied. I must say, and with the strongest conviction that I am right, that I consider this direction a very bad one. In the first place, there is no need of the tampon after once arresting the hæmorrhage by the means I have described. In the next place, if the vagina is tamponed, you have all the lochial discharges retained in it to decompose; you have, moreover, pressure upon the urethra and pressure upon the other parts that have just been subjected to severe contusion. But the safety of the patient requires you to guard against every possible danger of sloughing; and against decomposition, whether of the discharges or of the blood effused, at a time when the system is especially liable to the absorption of poison. I think the greatest danger in these cases is from septicæmia. So you make use of antiseptics. I was particularly struck by the fact that our distinguished countryman, Dewees, many years ago, recommended pyroligneous acid as an application to these cases of laceration, thus anticipating the antiseptic treatment by carbolic acid, now become so famous. My colleague, Professor Sayre, used compresses of oakum impregnated with carbolic acid, through which the discharges were allowed to ooze. We employed a wash of glycerine and carbolic acid, which protected the parts from fissure and excoriation by the irritant discharges or the urine.

It is an important point in the dressing not to detach the coagulum formed by the persulphate. It presents a black, ugly-looking mass, which you are strongly tempted to clear away; but you must never remove any part of it, except such as is completely loosened. If you avoid exciting it yourself, I think there is little danger of secondary hæmorrhage. Still further to guard against such an event, this patient was not allowed, for some time, to evacuate the bladder spontaneously, but the catheter was employed. After the coagulum had become detached the parts looked a little irritated, and an emollient was applied in the form of a poultice. The result you have seen.

In looking over the records of cases like this, I find they have been treated by bleeding and an antiphlogistic regimen. This case has been treated upon the principle, directly opposite, of restoring the exhausted vital powers as quickly as possible—by opium, the great restorative, alcohol, quinine, iron, and the most nutritious diet. I think she speaks well for the treatment.

Thus, gentlemen, I have occupied the hour in endeavoring to prepare you for an emergency which is not very rare, and may occur to any one of you—an accident which has heretofore been attended with a fearful fatality, both to mother and child, but which I hope a more enlightened practice may render less dangerous in the future.

Dr. W. T. Lusk has kindly furnished the following translation and abstract from Scanzoni's *Lehrbuch der Geburtshülfe*, published in 1867, and our readers will be interested in comparing his views with those of Professor Barker.—Reporter.

Thrombus of the vulva, or labial hæmatocele, occurs oftenest during or shortly after labor. Rupture of small vessels and slight extravasations beneath the mucous membrane of the genital organs, and into the connective tissue of the vicinity, are the pretty constant accompaniment of every normal labor. In fifteen cases of thrombus vaginæ, only one was connected with varicose veins. Tumor increases slowly, if vessel alone ruptures, but much more rapidly where there is at the same time considerable separation of the contiguous cellular tissue. In Scanzoni's fifteen cases the tumor occurred eight times before expulsion of child, six times during the delivery of the placenta, and once, in a twin case, between birth of first and second child.

Scanzoni lost only one of his cases: viz., from puerperal fever. Dangers are from ichorous decomposition of the retained clots. Pyæmia may be predicted in extensive extravasations which are not evacuated in good season.

Treatment.—The speedy evacuation of the blood from the cavity is the best remedy to avoid interminable abscess-formation. Scanzoni applies forceps and delivers immediately, and only incises the tumor first where it is likely to prove a mechanical hindrance to birth. After extracting child he puts pieces of ice and injects cold water into the vagina to control increase in size, and if this fails, tampon of compresses dipped in ice-water. Don't open so long as it continues to increase. If, after opening, hæmorrhage is excessive, use ice, and in case of failure plug cavity with charpie, and plug vagina.

Original Communications.

ANTERO-POSTERIOR SYMMETRY, WITH SPECIAL REFERENCE TO THE MUSCLES OF THE LIMBS.

By ELLIOTT COUES, A.M., M.D., Ph.D.,

ASSISTANT SURGEON, UNITED STATES' ARMY.

Art. V.

MUSCLES OF ARM AND THIGH, ACTING UPON FOREARM AND LEG.

We will first examine the extensor systems of the forearm and leg, in which symmetrical correspondences are preserved with admirable fidelity. The essential features of the main extensor of either limb are, the blending of one 'long' with two 'short' extensors at a common point of insertion into the principal bone of the segment to be acted upon. With minor modifications in the way of size, shape, and degree of fusion of different portions, this system is closely adhered to through an extensive series of animals. The 'long' muscle in both limbs always lies between the two 'short' ones.

In the forelimb of man the 'scapular head of the triceps' is the 'long' muscle, arising from the second segment above the forearm; it is the 'long direct' extensor cubiti, and consequently the 'indirect' flexor of the humerus. The 'inner' and 'outer head of the triceps' are the two 'short direct' extensors of the antibrachium, arising from the first segment above the forearm; these have no other action. These three blend in man rather high up on the humerus to form apparently a single muscle; the divisions of which nevertheless are marked for some way further down by tendinous interstices.

In the hind limb what is called the '*rectus femoris*' is the iliac head of the great extensor; the median 'long direct' extensor cruris, and consequently, when acting from below, the 'indirect' flexor of the thigh. What are called the 'vasti' are the two 'short direct' extensores cruris; the *vastus externus* corresponding to the outer humeral head of the triceps; the *v. internus* to the inner. It would seem, at first sight, that there was another part of the crural extensor not accounted for, viz., the "*crurœus*," whose presence in man and other animals has given rise to the collective name 'quadriceps extensor.' But the crurœus, when discerni-

ble at all, is merely a part of the vasti; and in man it is not distinguishable from the internal vastus. In certain lower animals the vasti form two great fleshy masses, lying on either side of the femur, and meeting on the median line in front, without any sign of a cruræus; they meet thus, and form a bed on which the rectus—always distinct and with pelvic origin—lies; the latter is sometimes separate to its very insertion into the tibia,* just as the scapular triceps of the *ornithorhynchus* has separate insertion into the olecranon. The little muscle called "subcruræus" is a specialty scarcely to be taken into consideration in a question of morphology. Nevertheless, if we desire to do so, we find its exact homotype in the little fascicle called *subanconeus*.

Such is the morphology and such the repetitive homology of the great extensors of the cubit and leg. But in addition to these there is an "accessory" extensor in each limb; which may not appear until it is pointed out. The *sartorius* is a singular muscle, and one of the most instructive, especially when taken into consideration with its anterior correlative. In man, it is a peculiar *flexor* of the leg. Arising from the anterior superior process of the ilium, it descends the thigh obliquely, winding around it, one might almost say, spirally, to gain the inner posterior aspect, form one of the inner "ham-strings," and be inserted into the tibia a little below the knee; it flexes the leg, with the superadded action upon the thigh that has given it the name of "tailors' muscle." And although this condition and office is substantially repeated in many animals, we might suspect, *à priori*, from the peculiarities involved, that here the muscle is in a morphologically false position. This is unquestionably the case: the sartorius is potentially the long accessory *extensor* of the leg as well as actually the indirect flexor of the thigh. The latter fact—that it is actually a femoral flexor—would, it seems to me, by itself prove the sartorius to be potentially a cnemial extensor; for we have no instance of a muscle in its morphological condition being at once a flexor or extensor of two consecutive segments of limbs: if it flexes one, it will extend the next, and conversely. Whenever such double flexion or extension occurs, it is safe to regard it as a teleological modification; just as we shall see that, *e. g.*, being tied behind a malleolus changes the action of certain muscles of the foot. Now it is easy to see, both how the sartorius comes to have its special action, and how slight a change in its direction would make it appear in and act its proper part of extensor cruris combined with flexor femoris. It is merely because it is tied down under the inner condyle of the femur; released from this confinement, and slipped up over the convexity of the knee, it would extend the tibia instead of flexing it. This view is warranted by comparative anatomy. In lowest animals, and in birds (in the latter without exception, so far as shown), the sartorius is a true extensor cruris. It arises, as in man, from the tip of the ilium in some instances; in others, especially in birds, its origin may be carried still further up the body, and the muscle appear as a plane arising aponeurotic from the spines of several presacral vertebræ.† It descends straight down the front of the thigh, parallel with and at length directly overlying, the rectus, narrowing meanwhile, to be inserted with the conjoined tendon of the rectus and vasti into the tibial tuberosity. Here it is seen in its true form and function. This is palpable, and would not have been enlarged upon, were it not that the view will be novel to some students of anthropotomy alone.

The anterior longitype of the sartorius only occurs as an anomaly in man; in fact, its absence is one among the distinguishing myological characters of *Bimana*. We occasionally find in the human subject what is called "a slip from the latissimus," going to some part about the elbow, but oftener higher up on the humerus, or even the scapula. This is in man the accidental appearance of a considerable and important muscle of brutes, present from the lowest monotreme to the anthropoid apes. It is a fasciculus given off from the lower (posterior) border of the latissimus, with or without a tendinous intersection at its point of departure from the larger muscle, and proceeding to a varying insertion near the elbow; sometimes to a humeral condyle; sometimes to the olecranon, more or less blended with the tendon of the triceps (and hence sometimes described as a fourth head of the latter); sometimes lower down on the back of the forearm, with distinct bony insertion, or merely spreading out on the fascia of the parts. This is the *omo-anconeus* (Owen), afterwards called, and usually known as, the "*dorso-epitrochlien*" (Duvernoy); it is the antitype of the sartorius. When inserted into the humerus its homology is not so plain; in other cases it perfectly repeats the position, relations, and function of the normal sartorius. It flexes, *i. e.*, retroducts the humerus, and extends the cubit. The fact that it takes its initial point from a muscle (latissimus) instead of arising from bone, is no valid objection, for its origin is virtually from the vertebral spines whence the corresponding part of the latissimus arises.

It might be suggested that the human *anconeus* is the remnant of this muscle, permanently detached from its real origin, and here extended obliquely from outer condyle to shaft of ulna; at any rate, I know of no muscle to correspond in the hind limb. But it is a serious if not conclusive objection to this hypothesis that the omo-anconeus coëxists in the same species with the anconeus proper. Such, if I recollect rightly, I found to be the case in the opossum; and I have lately seen the two muscles, both highly developed, in the duck-billed platypus.

The flexor systems of the two extremities offer apparent discrepancies, no less interesting than their evident correspondences. In the fore limb we find but *two* muscles, and these under what is apparently and almost certainly their morphological condition. In the hind the number is increased to *five*, which are, moreover, highly modified. The teleological guise so completely covers the crural flexors, that we find it difficult to discover their morphology. But one quasi-flexor has just been exposed as an extensor; and I hope to clear away at least a part of the obscurity that hangs over the others.

In the arm, there are two flexores cubiti: an 'outer' and an 'inner'; one for each of the two parallel bones that compose the forearm; the outer, called '*biceps*,' is for the outer bone—the radius; the inner, called '*brachialis anticus*,' is for the inner bone—the ulna. Of these, one, the outer,* is a 'long' muscle; it arises from the second segment above the one to be acted upon;

* By no means into the patella, to be afterward attached to the tibia by a so-called "ligamentum patellæ." The patella is a true sesamoid, not a "detached olecranon;" absent in some animals, in some others only represented by a few gritty specks.

† *Cf.* Cours. Osteol. and Myol. *Colymbus;* Mem. Bost. Soc. N. H., 1866 p. 167. The sartorius arises "from the spine of the dorsal vertebræ about opposite the apex of the scapula; passes downward and outward at an angle of 45°, overlying the *latissimus dorsi*, with a uniform width of about three-fourths of an inch, to be inserted, by a flattened tendon, into the inner aspect of the projecting spine of the tibia, half an inch *above* the knee joint. It is an extensor" [of the leg].

* Morphologically—not necessarily with reference to their actual mutual relations.

the other, the inner, is a 'short' muscle arising from the first segment above the one it acts upon. No arrangement could be more simple; none, probably, better represents a fundamental condition of the flexor system. This generalization is independent of special modifications in points of attachment, size, shape, etc. The "biceps" of man, *e.g.*, is correctly named; it has two 'heads,' from coracoid and glenoid, respectively, and one insertion, into tuber radii. But in many animals it is a unieeps; in others again it has one head and is 'biped'; when the two 'feet' may both have separate insertions into the radius, or the inner of them may be transferred to the coronoid process of the ulna. The *brachialis anticus* appears more constant: still it varies; *e.g.*, it may fork above, receiving in its cleft the apex of the deltoid, etc. Ignoring these and other specializations, we must regard the muscles in the bare condition just indicated.

In the hind limb, we clearly see two muscles or sets of muscles corresponding to the two foregoing flexors; they are those that go to form the 'outer' and 'inner' "hamstrings," respectively. The former consists of the tendon of the *biceps flexor cruris* alone, on its way to the fibular head; the latter is composed of the tendons of the *gracilis*, *semitendinosus* and *semimembranosus* together, passing to the inner side of the head of the tibia. The *popliteus*, moreover, though not forming a hamstring, is yet to be enumerated among these internal flexors. Of these, the outer (*i. e.*, the fibular) muscle presents no difficulty. It is unquestionably the longitype of the outer (radial) muscle of the arm. Both are symmetrically disposed; both are 'long' flexors; both act upon homologous bones. The femoral origin of one 'head' of the *biceps cruris* (which has given it its name) is to all appearance a specialization.* Typically, the muscle runs from tuber ischii to caput fibulæ without femoral attachment; as is generally the case lower in the vertebrate scale. Its modifications are wholly analogous to those that we have seen occur in the brachial biceps; both may be double- or single-headed, double- or single-footed.†

The muscles forming the inner hamstring, including the *popliteus*, may be homologized in two ways – both reasonable. The poplitæus, notwithstanding its low origin on the femur, and its very oblique direction, both of which tend to disguise it, is, as Wilder has shown, a perfect homotype of the brachialis anticus. It is the short direct flexor cruris, and goes to the inner of the two parallel bones of the leg. But in spite of these obvious correspondences, there are considerations that tend to throw balance of evidence in the other scale. Making such identification, we leave three large and important muscles without any correlatives in the forelimb. The gracilis, semitendinosus and semimembranosus are decidedly *the* inner flexores cruris; and are, moreover, very constant muscles throughout mammals and birds, while the poplitæus is not. I presume that if anatomists were only acquainted with animals lacking poplitæus, they would not hesitate to homologize the three inner hamstring muscles as a set with the inner flexor cubiti. Their pelvic origin seems to be the chief difficulty in the way, if not the only one; they are 'long' flexors, whereas they should be 'short' ones to correspond with the brachialis anticus. The gracilis is pubo-tibial, the other two are ischio-tibial; were they femoro-tibial, they would certainly be correlated with the brachialis anticus, and the poplitæus be considered as a supernumerary 'accessory' flexor. But change in the origin of a muscle is frequent; comparative anatomy furnishes many an instance; and even in the same species, we occasionally find a difference in this respect; while insertion on the other hand is more constant, and consequently a safer guide. It is only necessary, therefore, to consider the pelvic origin of these muscles as a teleological modification of a femoral one, to be enabled to refer them collectively to the brachialis anticus, and to regard the poplitæus* as a single "accessory" flexor that has no longitype developed in the fore-limb. At present I rather incline to this view, but, fully appreciating the objections to it, do not regard it as a satisfactory determination.

* Wilder (*op. cit.*, p 82) lays so much stress upon this form of the biceps cruris, as to identify only its 'long' or ischiatic head with the biceps brachialis; referring its 'short' (femoral) head to the supinator longus. But this view is, it seems to me, inadmissible. For independently of the impropriety of considering the biceps as a compound muscle, the supinator longus has, I think, an obvious homotype among cruro-tarsal muscles.

† But a double-footed biceps cruris is the rarest modification. I found it in the opossum, where the muscle sends a slip to the inside leg-bone, thus forming one of the *inner* hamstrings, as well as the outer hamstring; an arrangement instructively correspondent to that of the two-footed biceps brachialis of the same animal—where one foot goes to radius, the other to ulna.

* The suggestion that the poplitæus is a perverse indication of a pronator teres has been made; that it is the real homotype of the latter might be impressively argued by one holding that the tibia is the homotype of the radius. But he would need to be reminded that pronator teres is especially a superficial muscle, while poplitæus is one of the most profound.

Progress of Medical Science.

Treatment of Acute Indigestion.—Dr. Thos. K. Chambers, London, (Indigestions) advocates the following treatment of acute indigestion, based on pathological condition: The first condition is to spare the weakened organ as much as possible. Complete rest should be secured to it, by administering only liquid food whose absorption requires no action of the gastric glands. Weak beef-tea is the best diet, and rest of limbs best secures rest of the abdomen.

Let alcohol be avoided as a poison: it arrests still further the arrested vitality of the stomach.

Poultices and fomentations to the epigastrium relieve pain, and keep the patient on his couch. Mustard poultices and other counter-irritants do harm if there is inflammation, and less good than fomentation if there is not.

Emetics are wanted only when completely insoluble vegetable fibre is the cause of the disease. The mildest are the best, warm mustard and water.

The natural termination of indigestion in diarrhœa is an argument for the use of purgatives; but they should be mild, otherwise they hurry the augmented secretion through the intestines with a deal of griping, and yet leave the undigested matters behind. The most eligible form is that of enema with a little mustard in it.

In children, purgatives are apt to bring on a continuance of diarrhœa, if given for stomach-ache, and they also gripe a good deal. If necessary, let gruel enemata be given. In the acute indigestions of infants, minute attention should be paid to the quality of the milk. If the suckling mother or wet-nurse should be menstruating, have recently resumed matrimonial intercourse, or had any mental excitement, the milk too readily sours. The child should have it from a bottle, with a teaspoonful of liquor calcis to the tea-cup. The same addition may be made to cow's milk, if the child is fed on that. If there is diarrhœa, a teaspoonful of water arrowroot alternately with the liquor calcis.

The Nitrite of Amyl.—At a meeting of the Clinical Society of London, Dr. Austin communicated a case of angina pectoris relieved by the inhalation of nitrite of amyl.

CHRONIC INDIGESTION.—Dr. Chambers' favorite tonic in this affection is quinine, in two-grain doses in lemon-juice sufficient to dissolve it, and diluted with water to a convenient bulk. Its action seems to be principally on the mucous membrane of the mouth, œsophagus, and stomach, which it astringes and tones up to a healthy state, restraining the secretion of mucus, and making the special secretions more active. To quinine he usually adds from $\frac{1}{24}$th to $\frac{1}{10}$th of a grain of hydrochlorate of strychnia, unless there are some contra-indications to its use.

SPECIAL DISEASES FROM MENTAL STRAIN.—According to B. W. Richardson, M.D. (*Am. Jour. of Insanity*), diseases following upon mental shock or strain, are divisible into two classes. There is a *primary* class in which the mental shock stands out as the direct and only cause of the malady, and there is a *secondary* class in which the mental shock or strain appears only to increase or exaggerate symptoms of disease which pre-existed.

In the first class the diseases produced are the same as those which sometimes follow upon the receipt of physical injury to the nervous centres. The most distinct forms of disease of this nature with which he is familiar are, diabetes, paralysis (local or general), intermittent pulse, and arterial relaxation with arterial murmur. Diabetes from sudden mental shock is a true type, a pure type, of a physical malady of mental origin.

The class of cases where the symptoms due to nervous mischief are secondary, include, according to his views, syphilis, some chronic eruptions on the skin (psoriasis especially), cancer, epilepsy, and insanity itself.

Thus the symptoms of tertiary syphilis will recur on venereal excess, without any introduction of new venereal poison; thus eruption on the skin will recur from nervous shock; thus cancer so frequently shows the first signs of its presence in mental anxiety; and in two cases of persons predisposed to epilepsy, the first seizure was clearly traced to mental prostration.

CANCER A DISEASE OF THE NERVOUS SYSTEM.—Dr. B. W. Richardson (*Am. Jour. of Insanity*) asserts that cancer is primarily a disease of the nervous system, and that the local change we call cancer, with the ulceration which caps it, is the equivalent of the change and death of part after complete arrest, produced by division of nervous communication.

CAZENAVE'S DEPILATORY OINTMENT.—The subjoined safe depilatory ointment is recommended by the French surgeon, Cazenave:

Quicklime, one part; carbonate of soda, two parts; lard, eight parts. Mix to form an ointment.

CONIUM MACULATUM.—Leonard Wheeler, M.D., Lincoln, Mass. (*Boston Med. & Surg. Journal*), states that there is no useful preparation of this drug in our Pharmacopœia. The English have a good preparation in the succus conii, which is merely the juice preserved in one-third of alcohol. The variations in strength are not so great as to be a very serious objection, depending merely on the quality of the plants used in its manufacture. The best American preparation of conium, so far as he has been able to discover, is Squibb's Fluid Extract of Conium Seed. The most reliable specimen of the alkaloid conin is made by Merck, of London. It is not a colorless liquid, as the pure alkaloid is described, but perfectly clear, and of a bright reddish brown color. It has a strong, impregnating, disagreeable odor, is strongly alkaline, and exceedingly irritating. The taste is pungent and astringent.

AN INTERESTING EXPERIMENT.—Dr. Richardson recently delivered the concluding lecture of his course on Experimental Medicine for the session 1869-70. It was remarkable for a very curious experiment, which appears to show that there is a direct and almost immediate passage of substances in the gaseous form through all the tissues of the body, and especially through the coats of veins. Dr. Richardson introduced a fine tube through the nostril of a rabbit into the cranial cavity. Air, or carbonic-acid gas, pumped through this tube, instantly made its appearance in the right cavities of the heart. The carbonic acid darkened the blood and stopped the systolic action. Atmospheric air rendered the blood of the right side arterial, and restored the systole. At some future time Dr. Richardson promises to announce the results to which he may be led by following out this line of inquiry.—*Lancet.*

THE THEORY OF CONVULSIONS.—Professor Mantegazza (*Gaz. Lombard*), found that when rabbits are so far curarised that contraction of the voluntary muscles has ceased, convulsions are produced by the injection of concentrated urine, or a solution of urea, into the jugular vein.

When from such a rabbit a muscle is cut out, which no longer contracts on the application of galvanism, and dipped in a solution of urea, it begins to contract spontaneously. He therefore concludes that urea is a direct stimulant to the muscular substance. On this supposition, he thinks that convulsions may be divided physiologically into three kinds.

1. Central convulsions, as in tetanus, tumors of the central nervous system, &c.
2. Peripheric convulsions in traumatic neuralgia, neuroma, &c.
3. Idio-muscular convulsions in uræmia, and perhaps under the influence of special poisons in the blood.

THE ACTION OF URINE ON THE TISSUES.—Professor G. Simon (*Deutsche Klinik*) has made experiments on this subject. He remarks that it has been a dogma in surgery, that urine, whatever may be its reaction, has a destructive action on tissues not protected by an epithelial covering. He injected subcutaneously in rabbits pure acid urine. It was absorbed without any apparent bad effect. Operation wounds moistened with fresh urine healed by primary intention. When ammoniacal urine was injected, even though it had been filtered, abscesses were formed, and the skin over them became gangrenous. In view of these results, the gangrene which appears so rapidly in cases of infiltration of urine, must be ascribed to the mechanical action of the fluid driven forcibly among the tissues, so as to tear or compress the blood-vessels. In plastic operations on the urinary or sexual organs therefore, it is unnecessary to leave a catheter in the bladder so long as the urine is acid, whilst such operations should not be performed, if possible, when the reaction is alkaline.

CASES OF DIAPHRAGMATIC HERNIA.—In Dr. Bowditch's monograph, published in 1853, in which he analyzed eighty-eight cases, all that were recorded in medical literature between the years 1610 and 1846, the hernial opening was observed in the left side of the diaphragm forty-one times out of eighty-eight.—*Boston Med. and Surg. Journal.*

CARCINOMA OF THE MAMMARY GLAND.—Cancer of the breast, when excised, returns and destroys the patient, as a general rule. According to Sibley, some patients operated on lived fifty-three months, others only thirty-two months. He also says the disease usually recurs in about fifteen months after operation.—*Med. and Surg. Reporter.*

ARMY MEDICAL SERVICE ABROAD.

THE present war in Europe, it matters not how long it may last, will have a particular interest for the American surgeon. During our past struggle we have had an experience upon the battle-field unequalled in extent by any civilized nation; we have been enabled to solve many a difficult problem as to the proper care of the wounded, and can consequently claim the distinction of being, to a certain extent, experts in the matter. The ground, too, over which we have travelled has in all probability to be gone over again by our professional brothers across the Atlantic, and it becomes us to watch with solicitude their actions and results, in order to establish or to upset our own theories of army medical service.

The facts which have been developed in our experience during the last war have shown that we have also arrived at greater perfection in the care of our disabled soldiers than any other nation. Although with an army that sprang into existence as if by magic, and with a want of almost every preparation for the exigencies of the occasion, we managed not only at the end of the first two years to have in full operation a perfectly organized medical staff, but to obtain results which showed a very marked and gratifying diminution of the usual mortality. A comparison of statistics shows us that out of twelve thousand two hundred and ninety-one major operations performed collectively in the British and French armies in the Crimea, and the Union army in the Rebellion, over half belongs to the latter. When we add to this the statistics from the Confederate army, the number will probably be doubled.

The results of surgical treatment in the respective armies is not without its interest to the American army surgeon. The ratio of mortality in the French army was 72.8, in the British army 40.2, and in the Union army but 33.9. In the Schleswig-Holstein war, and in the seven weeks' war of 1866, the general average was 37.2. Thus it will be seen that American surgery leads the van in military as well as in civil service.

Let us glance retrospectively at some of the conclusions to which this experience has led us.

I. All matters pertaining to the medical care of an army must be intrusted to men educated for the purpose. The army surgeon should not only be the surgeon proper but the executive head of the hospital. He must administer all its affairs, and be responsible for all its shortcomings as to police, discipline, care of the sick and wounded, etc. Surgeon-General J. K. BARNES, while endorsing this fundamental principle of hospital government, truly says: "Never before in the world was so vast a system of hospitals brought into existence in so short a time. Never before were such establishments in time of war so little crowded or so liberally supplied. They differed, too, from the hospitals of other nations in being under the command of medical officers. Instead of placing at the head of establishments intended for the treatment of disease and wounds, officers of the line, who, whatever their other accomplishments, could not be expected to understand the requirements of medical science, and who with the best intentions in the world might seriously embarrass the action of the surgeon, as was sadly the case in the Crimean war, and has been since in the English hospitals; our Government, with a wiser discretion, made the surgeon the commandant of the hospital, and thus, while holding him responsible for the results of its management, put it into his power to make those results favorable. The medical staff can point with pride to the consequences of this liberal course. Never in the history of the world has the mortality in military hospitals been so small, and never have such establishments so completely escaped from diseases generated within their walls."

II. We have demonstrated that hospitals on the pavilion plan are the cheapest, best, and easiest constructed, and most commodious buildings of the kind, and that large edifices reconstructed are not adapted, all other things being equal, to the real wants of the sick and wounded. We have also proved that field hospitals, properly managed, lessen very materially the mortality of recent and severe wounds. Those which answered the best purposes were constructed of simple hospital tents.

III. The advantages of an ambulance system were clearly shown towards the latter part of our war. Under no other circumstances could its practical value be better tested where the area of battle-field was often very extensive, and where an army was frequently called upon to make a rapid change of base. Compelled to transport our wounded over the roughest of roads, we were early convinced of the use of every precaution in our means of conveyance that the urgency of the situation demanded. As a consequence the ingenuity of our race was taxed to its utmost to devise a suitable vehicle for the purpose. Many excellent ambulances were used, and we had an opportunity of seeing their merits tested at the recent Great Exposition,

where an American surgeon, Dr. Howard, carried off the prize.

IV. Our Sanitary Commission is acknowledged to have been the most perfect that ever had an existence, and its workings were attended with the most gratifying results. The reason for this was to be found not only in its perfectness of organization, and the energy of its managers, but in the fact that it only acted as an auxiliary to the medical staff of the regular army. Whatever of excellence, *per se*, there may be in such an institution, its legitimate object is aid rather than supplantation. Our soldiers will never forget the kindness of this Commission, and the anxious care with which it watched over their interests; the disposition it manifested to aid them in everything and anything that would tend to promote their physical comfort and welfare; how its members worked side by side with their surgeons in many a trying hour: but to the army medical department proper belonged the responsibility and credit of hospital construction, hospital management, and the medical and surgical care of the patients. On general principles this should always be so in every well-disciplined army. We are pleased to learn that a Sanitary Association has been organized in France under the auspices of Dr. Evans, of Paris, and another in Prussia, both of which take ours as their model.

V. Our late war has also been fruitful in various original appliances, instruments, operations, and methods of treatment, which have been utilized on a large scale and shown to be eminently adapted to the various emergencies which called them into requisition. It will not serve our purpose to refer to even the most prominent of these, as their mere enumeration would fill a volume. Suffice it to say that our writers on military surgery have made good use of this experience, and have, by the collection of statistics, the generalization and careful study of cases, established many facts in treatment which were heretofore only wrapped in a cloud of conjectural reasoning. Surgeon-General Barnes, with the able and talented assistance of Surgeons Woodward and Otis, has commenced the Medical and Surgical History of the Rebellion, and, as far as it has gone, there has been nothing found to compare with it in completeness. The Sanitary Commission, on its own behalf, has also issued two volumes of contributions from the volunteer medical staff, which are likewise monuments of learning and practical skill.

As Americans, we have reason to congratulate ourselves that our army surgeons have well performed their tasks; have added much to the general stock of military surgery; have, as far as results of operations in the army and the treatment of army diseases, shown the best record, and, without intending to patronize our transatlantic cousins, can bid them do likewise.

The Bureau of Vital Statistics of the Health Department of the City of New York is now thoroughly organized and in working order. Dr. Charles P. Russel, the Register, has shown himself to be eminently fitted for his position, and has instituted many important changes. Not the least of them is his system of reporting the number of deaths which actually occur during each day of the week, ending on Saturday at midnight. Accompanying this report are the daily meteorological observations for the same period. These reports are neatly printed in letter sheet for the purpose of being sent to the different scientific societies throughout the country, and also to such persons as are interested in accurate statistical data. We commend Dr. Russel's plan to the attention of Health Officers of other cities.

We present in this number a report of one of Prof. Barker's characteristic clinics. In our next we shall give another case of the same accident occurring in his service.

Reviews and Notices of Books.

Surgical Memoirs of the War of the Rebellion, collected and published by the U. S. Sanitary Commission. I. On the Wounds of Blood-vessels, Traumatic Hemorrhage, Traumatic Aneurism, and Traumatic Gangrene. II. On the Secondary Traumatic Lesions of Bone; viz, Osteo-Myelitis, Periostitis, Ostitis, Osteo-Porosis, Caries, and Necrosis. III. Pyæmia. By John A. Lidell, A.M., M.D., Brevet Lieut. Col. U. S. V., Late Surgeon in charge of U. S. A. Gen. Hospital, Inspector of Medical and Hospital Department of the Army of the Potomac, etc., etc. Edited by Prof. Frank Hastings Hamilton, New York. Published for the U. S. Sanitary Commission. By Hurd & Houghton. Cambridge: Riverside Press. 1870. 8vo.

The late war has been very fruitful in the production of many excellent practical surgical treatises founded on the experience therein obtained; but the present work is far superior to the majority, and stands, as regards intrinsic worth, almost alone. Indeed, as far as the special subjects of which it treats are concerned, it is the only one in point of completeness and practical value which has as yet grown out of our recent military experiences. Each section is treated by itself, but all have sufficient pathological dependence to be collected in one volume.

The subject of traumatic hæmorrhage, so important to the civil as well as the military surgeon, is discussed in all its varied and practical bearings, embodied in which are many original views and suggestions of the author. Concerning the wounds of blood-vessels, our author has given an exceedingly thorough and systematic account, leaving nothing to be desired. He makes five classes, each characterized by peculiar features: 1, punctured; 2, contused; 3, lacerated; 4, gunshot; and 5, incised. The division is a natural one, and by dint of much care the author has made it a very practical one. Traumatic aneurism receives its share of attention, in a pathological and therapeutical point of view especially; in the latter the author giving his preference for what is generally known as the old method. Parenchymatous hæmorrhage, long recognized by surgeons, receives here, for the first time in English surgical literature, an extended notice. Dr. Lidell makes for it three varieties, according as it occurs in the primary, intermediary, or secondary periods. The occurrence in the primary period is explained by a rigidity of the

walls of the capillaries, from previous inflammation of the soft tissues. When it takes place during the intermediary period, it is due to the imperfect closure of dilated capillary vessels when reaction comes on; and during the secondary period he agrees with Stromeyer in associating it with pyæmoid symptoms produced by thrombus. The traumatic lesions of bone comprise the second section. This, in our opinion, is the most valuable part of the work, as embodying the best account of the subjects to be found in the literature of surgery. Our author has had excellent opportunities for the study of the said lesions, both in military and civil practice, and has made the best use of the same in establishing many points original with him, and of immense value to the practical surgeon. He has taken great pains to point out the symptoms of the different bone lesions, their pathology and treatment, especially those referring to osteo-myelitis So little of real practical value is said of this latter pathological condition in surgical works, that the subject, as treated by our author, may be considered almost entirely original. Very few have examined the different conditions of this malady with more thoroughness than he, and none have studied it in the hospital ward and dead-house more faithfully and conscientiously. If we add to this, ten admirably excuted chromo-lithographic representations of the disease, in the appendix, we make this section a treatise in itself

The consideration of Periostitis, Ostitis, Caries, and Necrosis, is reasonably full. Attention is drawn, in the latter disease, to a generally unrecognized variety, the wet or mephitic osteal gangrene, the characteristic appearances of which are intelligently depicted.

The all-important subject of Pyæmia closes the volume. Our studious author has had a large clinical experience of this disease, and the following conclusions at which he has arrived are presented in full for such of our readers as may be interested in the subject:—I. Pyæmia is always connected with some local suppuration or its equivalent, that is, with some primary purulent depot as the source of infection. II. These primary depots may be either traumatic or non-traumatic in respect to origin, but traumatic cases occur much more frequently than non-traumatic ones. III. Traumatic pyæmia, in a very large majority of instances, is connected with some lesion of bone. IV. Purulent osteo-myelitis occasions pyæmia much more frequently than any other form of local suppuration, and it does so mainly because the pyæmic poison is absorbed from marrow abscesses much more readily than from any other class of abscesses. V. Pyæmia sometimes results from suppurative wounds of the blood-vessels, and in rare instances from suppurative lesions of connective tissue. VI. Pyæmia generally occurs between the fourth and twenty-third days after injury or operation, and thus corresponds exactly with the period of secondary hæmorrhage. It is met with but seldom, comparatively speaking, after the latter date. VII. Pyæmia is either acute or chronic in its course and duration. It may destroy life in two or three days, or not till the lapse of several weeks. VIII. Thrombosis is not essential to the production of pyæmia or of the secondary abscesses of the lungs, liver, spleen, etc., or of the secondary serous inflammations which characterize this disease. IX. Inflammation of the lymphatic vessels and glands constitutes a very frequent and important complication of pyæmia, but its pre-ence is not necessary or essential to the production of the disease. X. Pyæmia is a zymotic disease of septic character, and is closely allied to erysipelas and hospital gangrene. XI. The predisposing causes of pyæmia are debility, resulting from want and exposure, from scurvy, from malarial intoxication, and from chronic diseases in general. XII. The exciting causes of pyæmia are bad hygienic conditions, such as "hospital air" and "overcrowding," effluvia from filth, neglected wounds, and putrescent suppuration. XIII. The efficient cause of pyæmia is a subtle poison or contagium, of septic origin, which enters the circulation by absorption, and thus becomes disseminated through the whole organism. XIV. This poison, when diffused through the system by the circulating blood, exhibits a strong affinity or preference for certain organs or tissues, in which it kindles inflammatory irritation, and thus produces the so-called metastatic or secondary abscesses, and the so-called pyæmic or secondary serous inflammations. Thus the pyæmic poison, in the affinity which it manifests for certain organs and tissues in preference to others, is analogous in its operation to the poison of small-pox, typhoid fever, glanders, plague, and infectious disease in general. XV. Although pyæmia is a disease of septic origin, it is quite distinct from septæmia, properly so-called, such, for example, as the septæmia of traumatic gangrene, hospital gangrene, senile gangrene, etc. XVI. The prognosis in cases of pyæmia is always very bad. Almost all who are attacked with this disease perish. But few recover. XVII. Pyæmia requires a supporting plan of treatment. Quinine in doses of ten grains three or four times a day, and preparations of iron with alcoholic stimulants, p. r. n., and nutrients have proved beneficial. The oxalate of cerium has sometimes relieved the pyæmic vomiting, and bismuth the pyæmic diarrhœa, in a wonderful manner, in chronic cases. XVIII. But the prevention of pyæmia is a matter of the most importance in a practical point of view. This should be attempted by obviating the predisposing causes, by neutralizing the exciting causes, and by placing the patient beyond the range of the pyæmic contagium itself.

This volume being one of a series that shall contain surgical essays, we cannot do better for such as are to come than to wish them as interesting, practical, and as full of research and common sense. It is well printed, and is got up in the same style as the volume on medical memoirs, published three years ago.

A Treatise on the Theory and Practice of Obstetrics. By Wm H. Byford, A.M., M.D., Professor of Obstetrics and Diseases of Women and Children in the Chicago Medical College, etc, etc., Author of the Practice of Medicine and Surgery applied to the Diseases and Accidents Incident to Women; Chronic Inflammation of the Unimpregnated Uterus, etc., etc. New York: William Wood & Co. 1870.

This work was undertaken, the author informs us in his preface, with the view of furnishing the student and busy practitioner a concise and practical *treatise on obstetrics*. While acknowledging the excellence of many of the works extant upon the same subject, the author regards them as either too ponderous, too speculative, or entering too minutely into researches and discussions not desirable in the course of elementary instruction in the obstetric art. Hence, we find the volume before us devoted entirely to what is of practical and every day value to the obstetric practitioner. It cannot be denied that much of this practical information is drawn from the researches and investigations which are kept out of sight; but at the same time it is a great advantage for the student to have placed before him, briefly and perspicuously, the results of the labors of others, especially when presented by an author whose ability, experience, and success invest his opinions with a certain degree of importance, and warrant him in speaking as one having

authority. Professor Byford's great popularity as a teacher will ensure his work a favorable reception at the hands of those who have listened to his lectures, nor is there any reason to fear that their expectations will be disappointed, though we are of opinion that the book will be valuable chiefly to the student and the young practitioner.

The plan of the work is as simple as possible. It opens with a brief account of the pelvis and of the fœtal head, including all that is really of much value regarding measurements and the easiest means of obtaining them.

Sufficient space is devoted to a description of the female organs of generation, to the ovum, and to pregnancy and its varieties. On the subject of pregnancy and its relations to phthisis the author says:—

"The course of phthisis pulmonalis is often very decidedly influenced by the supervention of pregnancy. All the symptoms are generally ameliorated to a degree that is sometimes surprising, and occasionally the advance of tissual destruction in the lungs seems to be stayed. This improvement is in most instances only temporary, and after accouchement the march of the symptoms is more rapid, seeming to make up for lost time, and the patient dies in something like the same length of time as if there had been no interruption in the progress of the disease. In rare instances, and I think I have one of this kind under observation now, the woman remains greatly improved, and undoubtedly permanently benefited."

Dysentery, Professor Byford considers one of the worst complications of pregnancy, and especially to be dreaded after the middle period. Of the endemic fevers he says:

"The endemic fevers of miasmatic districts, in some years, are very severe upon patients attacked during gestation; but, like other forms, are very much influenced by occult and inappreciable causes to quite a difference in this respect. In the years 1846 and 1847, in one district near the junction of the Wabash and Ohio rivers, I was unfortunate enough to lose all my patients who had remitting bilious fevers complicated with gestation. The fever during those seasons continued uninterruptedly, under what I considered the most judicious management, until abortion or premature labor occurred, when rapid collapse was the sure precursor of death. In other seasons this fatal tendency was not observed."

In connection with this subject the reader will find a highly interesting chapter on the therapeutics of pregnancy, giving the author's experience, with various remedies as influenced by the pregnant condition. Veratrum viride is placed at the head of the list of arterial sedatives, and its "reputation of inducing abortion" Professor Byford believes to be founded on insufficient evidence. His opinion on the use of quinine during pregnancy will be of special interest to practitioners in the West and South. He says: "For several years I have entertained no apprehension of the injurious effects of quinine during gestation, and have resorted to it as freely as under other circumstances." On this point, we may remark, there is a wide difference of opinion among practitioners in miasmatic regions.

The author then takes up the subject of abortion and miscarriage, both of which are ably treated. He then passes on to labor and the various presentations and their appropriate management. There is nothing specially worthy of comment in this portion of the work, which will be found sufficiently full for all practical purposes. In regard to the position during labor, Professor Byford says he has accustomed himself to the English method of delivery on the left side, as well as the American method of delivery on the back, and gives his patients their choice between the two. In this connection we observe that some English obstetricians are declaring themselves in favor of the position on the back.

Regarding the use of anæsthetics in labor, a decided preference is given to ether, chloroform being reserved for cases where ether acts slowly or imperfectly. The author says: "As a general thing, I do not sanction the administration of ether until after the first stage is over, and withhold it as soon as the second stage is finished. But when the first stage causes a great deal more suffering than usual, it will sometimes be advisable to give it then. In tedious, difficult, and operative cases of labor, I feel as much under obligation to use the anæsthetic, and make as profound impression with it, as in the performance of any of the more painful surgical operations, and for all the same reasons." When given imprudently, Professor Byford is of opinion that anæsthetics lessen the efficiency of the pains so much that "the labor is protracted very considerably."

Concerning the indications for the use of forceps, the author has the following remarks:—

"Time is no measure of the damage likely to result from the lodgment of the head in the pelvis. In four hours, a head arrested from impaction, under the influence of efficient labor pains, may and would be likely to awaken a very destructive form of inflammation, and thus irreparable damage; but a head lodged in the pelvis on account of the want of force to push it through a pelvis well proportioned to it, in size, may remain double the time without serious damage. . . . As before intimated, we cannot derive our indications for obstetrical practice from time, but must watch the symptoms. . . . Hence, I do not believe that it is philosophical to say that if the head remains stationary for four hours we must remove it."

The remainder of the volume is devoted to natural labor in multiple cases, attentions to the child, the puerperal condition, the conduct of labors calling for instrumental aid, hæmorrhage, inversion and rupture of the uterus, prolapse of the cord, and puerperal convulsions.

Considering the special object the author had in view, of being at the same time concise and comprehensive, it must be admitted that he has done his work very well indeed, and given the profession a book that will be very acceptable, though the pleasure of reading it would be much greater if Professor Byford had given a little more attention to his style of writing. His sentences are often awkward and even inexcusably ungrammatical; but it is gratifying to find some improvement in this respect on his previous works, and in spite of literary deficiencies the author rarely fails to make himself pretty well understood. The wood-cuts with which the volume is liberally supplied are rather coarsely executed, but answer the purpose of illustration, and render material service in following the author's descriptions and demonstrations.

STATISTICS OF INSANITY.—In France, there were in 1866, according to the statistical returns of the Government, 50,726 insane, and 39,953 idiots and cretins; in England, 1868, by report of the Commissioners in Lunacy, 33,213; and in the United States not less than 60,000.

CLINICAL TEACHING IN INSANITY.—To Professor Griesinger we are indebted for the practical solution of the question of clinical teaching in insanity, in the year 1863.

NEW YORK MEDICAL JOURNAL ASSOCIATION.

STATED REUNIONS, APRIL 15 AND 22, 1870.

DR. ISAAC E. TAYLOR, PRESIDENT, in the Chair.

ANTIPHLOGISTICS IN DISEASES OF CHILDREN.

DR. JACOBI made some remarks upon *Antiphlogistic Treatment in Diseases of Children*, published in the RECORD of May 2 (p. 97), of August 1 (p. 289), and in our present issue.

DR. GEO. T. ELLIOT.—Though I did not know the subject of to-night's discussion, yet the name of Dr. Jacobi was a sufficient attraction. One thing which I have always had occasion to admire in his way of dealing with the problems of disease is his close adhesion to physiology, so happily shown in his work on "Dentition and its Derangements." But there have always been some questions of practical therapeutics in which I have had to differ from him; and it seems to me that this difference between us has been a growing one—his faith in therapeutic means and powerful doses growing stronger, while I have been more and more inclined to leave matters to nature and to milder methods.

With regard to venesection in infancy, I am glad to find that we agree. There is great danger in Chambers' advice to apply a leech to the belly, and then a poultice into which the leech-bite is to be allowed to bleed freely. I fear the catalogue of those who have been led by the elegance of Dr. Chambers' style to make trial of this practice, would show too many cases of a fatal result. I am in terrible doubt, often, when I drag children by forceps into the world, presenting every appearance of congestion of the brain. I cannot make up my mind to apply a leech over the mastoid process, nor do I often let fly blood from the cord. But here I speak with modesty.

As to extravasations, their tolerance by the fœtal brain has surprised me, and it is a question whether they are not far more frequent than commonly supposed.

I was struck by the doctor's statement that the heart is most frequently diseased in fœtal life. I have been interested for many years in autopsies of still-born children, and my experience is that diseases of the heart have been much rarer than those of other organs—indeed, very rare. I have met more frequently diseases of the kidneys and of the ureters—leaving out of view, of course, all syphilitic and tuberculous affections.

With regard to uric acid infarction, I have the idea that if every child were placed, as soon as born, to a full breast, this infarction would not be found in case the child should die by accident a day afterwards. The reason is that children pass, relatively, some six times as much urine as adults; and the amount of urine they excrete is in direct proportion to the supply of milk. Let the infant, then, be put at once to a full breast, so that the water may wash out the kidneys. But this is of little practical importance. Much more important is it at once to secure the balance of nutrition in the child's favor.

In the administration of chloroform to infants I have not found the difficulty that has been mentioned. I remember giving it twice in one day to a baby nine days old, for the reduction of hernia, and there was no trouble.

In cases of infantile tetanus, I think we have, in this country, too much neglected the thorough examination of the spinal cord. I recall always with interest a fatal case of this disease in a young child, where I found at the autopsy, to my surprise, an extensive hæmorrhage, the blood having passed down to the bottom of the vertebral canal.

A great deal has been said by the Doctor regarding the action of cold water. Too many people still fail to distinguish between the two opposite methods of applying it—the one continuously so as really to get the effect of cold; the other by a wet compress left unchanged, so that you very soon have a warm poultice. Of the great value of cold in acute conjunctivitis, whether of the new-born or of the adult, there is no doubt. But if you attempt its application to infants, especially in hospital practice, you will find in the majority of cases that the attendant is neglectful, and that you are poulticing the eyes. The popular "cold-water" cure of sore throat is, of course, nothing but poultice-treatment. I often direct a flannel bandage, wrung out of water, to be worn around the abdomen, and in many disorders of the abdominal viscera in women, I am sure that this treatment (a poultice) will do much good.

In the application of cold to the head in the cerebral disorders of children, upon which Dr. Jacobi's remarks seemed to me extremely important, I have met with the same difficulties of which he speaks. With very restless children, where the direct cold application produces great irritation, it has been my habit to apply a warm evaporating lotion, and then let the nurse gently fan the head. In graver cases, however, it becomes necessary to resort to the ice-bladder, or the steady dropping from a siphon above the head.

The Doctor said that his great reliance in diphtheria, apart from tracheotomy, was ice. I can bear personal testimony to the great comfort derived from this, for it is comparatively few years since I myself experienced it in an attack of scarlet fever. But I cannot accord it the same value as an exclusive treatment. Far rather would I testify to the great value of oxygen gas, enabling the child to get along with a less amount of air; and to Dr. Jacobi is due the credit of its first employment thus in this city. I shall by and by have something to say upon this subject myself.

I should certainly differ from the Doctor as to the propriety of applying ice to an inflamed joint in rheumatic synovitis. What is the danger? Metastasis is rare, I admit, but it occurs; I have seen it even without any exciting cause. I remember the case of a gentleman who lay suffering excruciating pain in one wrist, which was greatly swollen. In a flash the pain left this wrist entirely, to attack the other in the same style. I have seen but three cases in which acute rheumatism has attacked the meninges of the brain. Two of these did well. The third was that of a near friend of mine, where suddenly, and delightfully as it seemed, the pain and swelling left the joint, when symptoms of meningitis set in and he died unconscious within forty-eight hours. Is the experience of the world—is the experience of all these gouty and rheumatic generations—to go for naught? What can we do in this disease? Render the urine alkaline as soon as possible. While the rheumatic fever is expending its force upon a joint, it is in a safe place, for there is little danger that pus will form. Let it work there while we control the pain by hypodermic injections or alkaline fomentations, and meantime are pushing our attack upon the very head and front of the offending by means of the alkaline treatment. It will be understood that I give these arguments simply to present the other side of the question. I am perfectly able to offer arguments against those I have just stated. I am perfectly able to say that we should not hastily condemn the cold applications, but await the testimony of statistics; only I say let not the material for such

statistics be myself, or my patients, or my friends—*fiat experimentum in corpore vili.*

Dr. Carroll called attention to a valuable article in the last number of the *British Med. Journal*, upon the use of cold water in typhus and typhoid fever.

Dr. A. H. Smith.—I have been especially interested in the remarks upon counter-irritation. While not disposed to disparage the *rôle* played by the nervous system in the action of counter-irritants, I yet think that their principal effect is produced through the circulation; and there are some points with regard to this which might be more fully brought out. The supply of blood to the different parts of the body is evidently dependent chiefly upon the calibre of their capillaries and arterioles; so long as this is normal the distribution of the blood will be normal; but the moment the capillaries of any one organ are either dilated or contracted, that moment the entire circulation of the body is deranged. For example, let us suppose that, in a given unit of time, four pounds of blood pass through the entire capillary system, and that in that time one pound passes through one of the inferior extremities. If, now, we immerse that extremity in a hot mustard bath and dilate its capillaries one-half, it will allow one pound and a half of blood to pass through it, and we have abstracted half a pound from the rest of the circulation. If, on the other hand, we plunge it into cold water and contract its capillaries, we diminish the amount of blood that can pass, and to that extent produce congestion of the rest of the system—most probably of some of the internal organs. So in an extensive burn, where the superficial capillaries are occluded by the height of the inflammation, we have congestion and inflammation of the lungs. I think that, similarly, very decided changes in the circulation might be produced by changes in the pressure of the atmosphere upon the surface of the body, since this would act chiefly upon the cutaneous capillaries. In considering the effect of remedies upon the circulation of a part, as in the case of opium mentioned by Dr. Jacobi, we must have regard not only to their direct effect upon the peccant organ, but, as well, to that upon the system generally. For if an organ be congested, general relaxation of the capillaries of the body will relieve it, and *vice versâ*.

Dr. Messenger.—I was called to see an old gentleman in Brooklyn with double pneumonia. He was in a very critical condition, temperature in the axilla 105°, pulse frequent, breathing very frequent and very short, skin cyanosed; speedy dissolution was expected. Having much confidence in the curative power of quinine, I began by giving a dose of twelve grains, and then gave six grains every hour for twenty-four hours. I was certainly very much surprised by the favorable effect produced in that time—the reduction of the temperature by three degrees, the lessening of the frequency of the pulse and of the rapidity of the respiration. I had also cupped the patient over the chest; but I attributed his relief from the danger of imminent dissolution to the quinine. In the febrile diseases of children, and especially pneumonia, I have used it a good deal, and I think it should be used much more frequently than it is.

I have myself suffered much from the effects of intermittent fever in years past, and I have found remarkably good results from large doses of quinine—twelve to twenty-four grains—not very often repeated. Within a few days I have passed through a critical sickness from the effects of a malignant pustule on the hand. I took twelve-grain doses of quinine, several of them in the twenty-four hours, with the effect of allaying the fever and restlessness; and to-night I am feeling as well as before my illness, although the hand is still sore. As to the use of *dragées*, I cannot myself take large doses in any other form without nausea—except in extract of licorice—and I have always found them efficient.

Dr. A. C. Post.—I have been in the habit of using blisters to a considerable extent in the treatment of the inflammatory diseases of children, and I am fully satisfied in my own mind that they have produced salutary effects. If a blister is applied at the proper time and removed at the proper time—for everything depends upon that—if not allowed to remain on longer than an hour and a half or two hours, when vesication will not appear until after its removal, then instead of its producing constitutional disturbance, I have found it decidedly anodyne, putting the child to sleep, and tranquillizing the pulse. But the consequences of leaving the vesicant on the skin for too long a time are very formidable. I have seen some cases where I think children have died from the effects of blisters, and others where they have suffered great tortures.

Dr. Elsberg.* — Dr. Jacobi's remarks commend themselves to every practitioner as the results of a wide practical experience. I will not attempt to follow him into detail; but there is one thought regarding the general tendency of his views which I would like to express. It seemed to me that he did not sufficiently dwell upon the fact that many diseases, especially many inflammatory diseases, are self-limited, and require no drug-interference on our part, no dosing whatever. Making this your first rule, *never, in any disease, to interfere by means of drugs without a distinct therapeutic indication or object*, then make your second that stated by Dr. Jacobi, *to give remedies for effect, i. e., to accomplish that object.* Do not mind the doses of the books, but get the effect before you stop their administration. This is made necessary by the greatly differing susceptibilities of different individuals. I am sure that I have thus tentatively given doses of the drugs that have been mentioned which would sound almost frightful, while in other cases I have gained the full effect desired from doses that would seem insignificant.

In the matter of blood-letting I think we have gone too far toward the negative extreme. With this, as with most other antiphlogistics, the great point is to use it as an equilibrifier, a *balancer* of the circulation. I am sure a physician ought never intentionally to weaken a patient; nor is it true that abstraction of blood, within proper limits, always and necessarily reduces the strength of the system. What it reduces, and what we want it to reduce, is abnormal or irregular action, disproportionate vascular excitement or congestion, in order to restore the equilibrium of the circulation and the equilibrium of all the processes of life. It is this equilibrium that we aim to establish, whether our object be to affect the function of any organ, or to effect tissue-metamorphosis. It is the active local determinations of blood, the arterial excitement of inflammations, that can be beneficially modified by antiphlogistic treatment, and for which I think bleeding indicated. The proper time for bleeding is the early stage of the disease, and the quantity abstracted should not be too large. Local depletion has all the advantages of venesection, except in some cases; convenience of application, and promptness of action; and wherever it can be employed it should be preferred, just because it is a less general, less severe, and (on account of the smaller quantity of blood withdrawn) a less consequential interference. In cases of active or passive congestion of important organs in robust, plethoric individuals,

* The report of Dr. Elsberg's remarks, revised and expanded by himself, at his special request.—Reporter.

apoplexy, puerperal convulsions, etc., a prompt venesection has doubtless, I think, saved lives; and, on the other hand, by omission to bleed, lives have been lost; although, of course, in all cases, so powerful a remedy must be used with caution, as, for instance, in senile apoplexy.

DR. JACOBI.—I would ask, what are those self-limited diseases that will not permit any interference?

DR. ELSBERG.—Their list is so much longer than that of all other diseases, that it would be easier to name the latter. In a general way we may say that all endemic, epidemic, infectious, and contagious diseases are naturally self-limited; that inflammation shows a tendency toward delitescence and resolution upon removal of its exciting cause; and that all the phlegmasiæ, when not of too high grade, not of too rapid course, or not threatening vital organ and function, may safely be permitted to get well with hygienic antiphlogistics, as rest, cold, regimen, etc., without drug-interference. Of such practice, even the treatment of pneumonia may serve as a type. The diseases not self-limited are those in which tissue-destruction, and important tissue-destruction, is going on so rapidly that our prompt interference may be required to check it. It is therefore that venesection, the *summum remedium* of our forefathers in the treatment of inflammations, is more frequently necessary in meningitis than in pneumonia, and more frequently in pneumonia than in erysipelas. In the presence of so many students of medicine and recent graduates as I see here this evening, it seems to me that Dr. Jacobi's rule of energetic and heroic drug-medication requires some qualification which, I doubt not, he acts upon in his own practice. As the aggregate tendency of all the forces of the living organism is toward the best possible result attainable under all the conditions, it is the physician's duty to place his patient in such circumstances, and to favor or supply such conditions, as allow or promote recovery of health. Whenever, in pursuit of this duty, drugs are given, it should be done with a distinct object as to their effect, but in no case should the physician become a routine-doser, a *druggist* of diseases!

DR. JACOBI.—If there is any disease which is not self-limited in infancy and childhood, it is just this pneumonia; and therefore, in my opinion, if there is any disease which demands interference it is pneumonia. The doctor has evidently been remarking upon the regular croupous, and so-called lobar, pneumonia, which we see in adults, and which we see immediately after birth, in the first month or two. There we can say that it is a disease which, after invading the organism, will run its regular course in a given time. Yet even there I hold that, as a rule, we ought to interfere, on the general principle that the longer the fever lasts, and the higher the temperature, the greater is the danger. But the pneumonia of infancy and childhood is of the catarrhal, lobular character, and it is not "self-limited." A pneumonia will last seven, eight, nine days in an adult; and in a child it will last seven, eight, nine months. It is not "self-limited" for the reason that it is not *one* pneumonia, but many pneumonias; there may be as many of them as there are bronchial ramifications affected. Therefore I say, that where we have a disease so dangerous in its consequences—likely to lead to consumption, even—we must follow it up, and, if possible, prevent new attacks by relieving the bronchitis; and if a new attack comes on we must relieve it, because relief for that is prevention for another.

DR. J. B. REYNOLDS.—I consider it my duty, as I have been associated with Dr. Jacobi in the same institution, to endorse the general tenor of his remarks upon antiphlogistics in children's diseases, and especially upon the use of cold water, quinine, and ergot. With regard to the treatment of catarrhal affections of the eye by cold water, some difference of opinion was expressed last Friday. I find that in forty cases of very severe catarrhal conjunctivitis which I have had under treatment within the last four months, cold water, constantly applied, was the only remedy we had occasion to resort to. All of the cases recovered, and in not one was there any ulceration. In the treatment of pneumonia, as it commonly occurs in the children found in our public institutions, I know that it is very seldom necessary to apply any marked counter-irritation; but the constant and free use of quinine and carbonate of ammonia, with, of course, plenty of nourishment and good hygiene, has brought about recovery in many cases that had seemed hopeless, and in others has restored them to comparative health and comfort. Dr. Jacobi will remember a child lately brought to the clinic with countenance livid and respirations 100 a minute. Large doses of quinine and camphor were given, and the child is now alive and perfectly well. I have had good opportunities, in public institutions, of testing the value of the large doses of quinine, and I must heartily approve of them. I must approve also of employing counter-irritation but rarely in acute troubles, though we may fall back upon it in chronic, subacute inflammations.

The meeting adjourned.

Medical Items and News.

MISS GARRETT.—This indefatigable Englishwoman has just passed her final examination for the degree of Doctor of Medicine in Paris.

QUADRUPLETS.—Dr. R. H. Tarlton, of Martinsville, Ind. (*Am. Practitioner*), recently delivered alive three females and one male, which soon died. There were two placentas. The mother made a good recovery.

THE ALBANY MEDICAL COLLEGE MUSEUM.—Dr. T. D. Crothers (*Med. & Surg. Reporter*) writes that the museum of the Albany Medical College has the largest collection in Osteology in America (if not in the world). Of fractures alone there are over seven hundred specimens. The late Dr. Alden March made a collection of 128 specimens, illustrating diseases of the hip-joint, and fractures of the neck of the femur. In Prof. McNaughton's collection are five giant skeletons, called by the students "Highland Brothers." They are over six feet high. The whole number of specimens catalogued is 3,549, which, together with those deposited, would swell the number to 5,000 and over. These specimens have been gathered within a period of thirty years.

DEATH OF AUZIAS TURENNE.—This renowned Swedish syphilographer died in June of pneumonia. After his death more than fifty scars were discovered on his body where he had inoculated himself with the syphilitic virus.

A CENTENARIAN.—According to the *Gazette Hebdomadaire*, there is now living in Warsaw a man 112 years of age. Only three years have elapsed since his hair became gray, and when he was 93 years old he had a son by his second wife. His father lived 120 years, and his grandfather 126 years.

DEATHS FROM SMALL-POX.—Russia, in the 69 years commencing with 1801, has lost, by small-pox, 10,350,000 children.

A Valuable Prize Awarded.—MM. Paulet and Jules Sarazin have been awarded a prize of the value of £100, by the Academy of Sciences, for their excellent treatise and atlas of surgical anatomy.

The Scottish Brain.—Dr. Peacock announces that the average brain weight of Scotchmen, between the ages of 20 and 60, is 50 ounces.

An Appointment in the Paris Faculty of Medicine.—M. Chauffard has received the appointment of professor of general pathology in the Faculty of Medicine of Paris.

Cincho-Quinine.—At a late meeting of the California Pharmaceutical Society, all the members agreed in noticing the absence of *quinia*, and the great preponderance of *cinchonia* in the "cincho-quinine" manufactured by Nichols & Co., of Boston, Mass.

Paris School of Medicine.—Dr. Charles Daremberg has been elected to the newly vacated chair of History of Medicine, in the Faculty of the Paris School of Medicine.

Ipomœa Simulans.—Daniel Hanbury, F.R.S., Honorary Member of the Chicago College of Pharmacy (*The Pharmacist*), finds that one of the most remarkable kinds of jalap is a tubercule imported a few years ago for the first time from Tampico, and thence called *Tampico Jalap*. He ascertains that it is a production of the State of Guanajuato, Mexico, where it grows along the Sierra Gorda, in the neighborhood of San Luis de la Paz. He has also drawn a diagnosis and description of the plant, which is called *Ipomœa simulans*, from the remarkable similarity which the plant bears in foliage and habit to the true jalap (*Ipomœa Purga*, Hayne).

The Association of the Alumni of the Massachusetts College of Pharmacy.—This Association held its first meeting on Friday evening, June 24th, 1870. The following officers were then elected: *President*, Prof. G. F. H. Markoe; *First Vice-President*, H. W. Lincoln; *Second Vice-President*, J. T. Brown, Jr.; *Secretary*, T. Doliber; *Treasurer*, C. H. Bassett; *Executive Board*, J. C. Lowd, C. B. R. Hazeltine, A. B. Warfield, E. S. Kelly.

The First Medical Journal Published in this Country.—The first medical periodical published in America was the *Medical Repository*, commenced in 1797, in the city of New York, and edited by Drs. Saml. L. Mitchell, Edward Miller, and Elihu H. Smith.

Chicago Sewerage.—This flourishing Western city has 110¼ miles of sewers.

New York Ophthalmic and Aural Institute.—This institution, under the charge of Prof. H. Knapp, has passed through its first year successfully, and from the yearly report we learn that there have been during the year ending April 30th, 1870, 1,828 patients treated in the Dispensary, of which number 1,387 were for eye diseases, and 441 for ear diseases. One hundred and forty-three persons were treated as resident patients.

Two hundred and twenty-eight operations have been performed, of which 181 were for eye diseases, and 38 were for ear diseases. There were 56 operations for primary (52) and secondary (4) cataract; for squint, 138; enucleation of eyeball, 24; and operations on the lids, 58.

Extirpation of polypoid growths, 14; extirpation of hypertrophied tonsils, 22.

At the regular annual meeting of the Board of Trustees, held May 23d, 1870, the officers were re-elected for the ensuing year.

Insane and Idiotic Persons in Michigan.—In this State there were in 1850, insane, 133; idiotic, 189. In 1860, insane, 251; idiotic, 333; and the coming census for 1870 will probably show not less than 600 of each.

Michigan State Medical Society.—The fourth annual meeting of this flourishing State Society was held in the Senate Chamber at Lansing, June 8, 1870. Several important medical papers were presented and ordered for publication. The following officers were elected for the ensuing year: *President*, I. H. Bartholomew, M.D., Lansing; *Recording Secretary*, Geo. E. Ranney, M.D., Lansing; *Treasurer*, D. O. Farrand, M.D., Detroit; *Corresponding Secretary*, Geo. W. Topping, M.D., De Witt. Two delegates, for the first time, will be sent to the next meeting of the N. Y. State Medical Society.

An Interesting Case of Hydrocephalus.—At the late meeting of the Michigan Medical Society Dr. Geo. E. Ranney, of Lansing (*Mich. Univ. Med. Jour.*), reported an interesting case of "Hydrocephalus." It had its origin in cerebral meningitis, occurring at the age of four weeks in a child born of healthy parents, and caused death at the age of two years. After death the circumference of the head was found to be thirty-six inches.

Medical Journals in the United States.—There are at the present time about forty medical journals published in this country.

The University of California.—The Board of Regents of the University of California have nominated Prof. D. C. Gilman, of the Scientific School of Yale College, for its President. An application has been made by the "Toland Medical College" to the Regents of the University, for admission as a department in this institution.

Copper Mines in the United States.—The Calumet and Hecla mines of the Portage Lake district, Lake Superior, will produce this year 12,000 tons of copper. This alone is sufficient to supply consumption.

The American Chemist.—This is the title of a journal which will be devoted to analytical, theoretical, and technical chemistry, and is under the editorial charge of Chas. F. Chandler, Ph. D., and W. H. Chandler. This journal is to take the place ofthe American reprint of the *Chemical News*. Messrs. Baldwin & Co. have purchased of W. A. Townsend & Adams the subscription list of the reprint of the *Chemical News*, and will present everything of value from the English edition in this new independent journal. The plan of the *American Chemist* includes, in addition to such original articles as may be available, the reproduction of all such foreign and American matter as may be thought to be of interest to American chemists.

The July number, containing forty pages of reading matter, has been received, and bears evidence of careful and able management on the part of its editors.

Sulphurium.—This defunct element—since suggested as thallium, discovered by Crookes in 1862—was discovered by Joseph Jones in 1857, in residues of a sulphuric acid manufactory.

Death of a Celebrated French Physicist.—At the last meeting of the Faculty of Sciences at Paris, the President announced the death of Prof. Lamé, a member of the Institute since 1843. Among his very many published works, those on mathematics and on the elasticity of bodies are the most celebrated.

First Importation of Cinchona Bark from Java.—It appears that, toward the end of last year, a quantity of some 930 lbs. of this bark has been exported from

Java to the Netherlands. From analysis made by Dr. B. Moens, in Java, this bark contains from 2.4 to 7.5 per cent. of alkaloids, of which quantity 0.59 to 3.67 is quinine. The loss of weight occasioned by the drying of the bark has been found to amount to 66 per cent.

There is every prospect that within some 6 or 7 years hence Java will largely export this drug; and the cultivation of the cinchona trees is also to be extended to Sumatra, Celebes, and the Moluccas.—*The American Chemist.*

NEW WORK ON ANALYTICAL CHEMISTRY.—Wherever, on the Continent, French is read, the following work, of the second edition, is highly eulogized: "Précis d'Analyse Chimique Qualitative," par Gustave Chancel, Ph.D. etc., Doyen de la Faculté des Sciences de Montpellier.

A MAMMOTH INFANT.—The birth of an eighteen-pound girl is reported in Douglass, Mass.

THE DISCOVERY OF ANIMAL ELECTRICITY.—Galvani discovered, in 1791, that muscular contractions followed the connection of the nerve and muscle of a frog by a heterogeneous metallic arc, and from this fact he was led to declare in substance that animals have a special, independent electricity, deserving the name of *animal electricity*. In 1827, M. Nobili, having constructed a very sensitive galvanometer, was enabled to detect, without doubt, the existence of an electric current in the frog. He observed that when the needle was placed in the circuit it was deviated from 30°.

THE WOMAN'S MEDICAL COLLEGE OF THE N. Y. INFIRMARY.—The winter session of this Institution commences on the 1st Monday in October, and continues twenty-four weeks. Through the indefatigable industry and perseverance of Drs. Elizabeth and Emily Blackwell, the founders of the school, females now have the opportunity of getting a thorough and practical medical education, under efficient male and female professors. For further particulars, students may apply by letter to Dr. Emily Blackwell, Secretary of the Faculty, 128 Second avenue, New York city.

A NEW ANÆSTHETIC.—M. Sauer, a Berlin surgeon-dentist, advocates the use of a mixture of protoxide of nitrogen, chloroform, and atmospheric air, in the following proportions: Liquid chloroform, six grammes; atmospheric air, three-fourths of a litre; and protoxide of nitrogen, sixteen litres.

HUMAN VACCINATION VERSUS ANIMAL VACCINATION.—To show how low the theory of animal vaccination has fallen, the following declaration by French medical officers is appended: "We, the undersigned, medical officers of the Bureau de Bienfaisance of the Seventh Arrondissement, after examining, watching, and comparing the results of the vaccination services established at the Mairie of the Seventh Arondissement, with vaccine lymph taken from the heifer, are of the opinion that the results are most unsatisfactory, even in the case of infants, and that this system ought to be discontinued; and request that Jennerian lymph be placed at their disposal."

A CASE OF TRIPLETS.—Dr. L. L. Jones, of Deerfield, Mich. (*Med. and Surg. Reporter*), writes that he was summoned, June 25th, to the bedside of a multipara, æt. thirty-two, weighing in ordinary health 115 pounds, and found her in labor for the fourth time. She was delivered of *three* boys in quick succession. The first weighed six pounds four ounces; the second five pounds ten ounces; and the third five pounds two ounces. The first two were attached to a common placenta, the third had a placenta of his own. Seventeen pounds of baby all doing well.

CROUP.—Although croup was known to Hippocrates, there was no clear description of it earlier than that of Blair, in Scotland, 1718. In 1765, Home, of Edinburgh, also gives it a distinct place in the family of diseases.

Of all the titles given to this disease, Dr. J. H. Hobart Burge, of Brooklyn, N. Y. (*N. Y. Med. Jour.*), prefers *laryngo-tracheitis*, as expressive of the fact that it is an inflammation of the larynx and trachea. In this he but conforms to the views of Cullen, Home, Dickson, Peaslee, Condie, and others.

N. Y. STATE HOSPITAL FOR DISEASES OF THE NERVOUS SYSTEM.—The trustees of this hospital have secured the large and well-appointed building at the southwest corner of Second avenue and St. Mark's place, N. Y. City, for the reception of patients. It is the design of the trustees to have an out-door department, at which patients residing at their own homes can attend and receive gratuitous treatment. The capacity for in-door patients will be about twenty-five beds. The medical officers are: Dr. W. A. Hammond, *Physician in Chief;* Dr. Reuben A. Vance, *Asst. Physician;* Dr. T. M. B. Cross, *Resident Physician.*

STONE IN THE FEMALE BLADDER REMOVED BY DILATATION.—Mr. T. Pridgin Teale, of Leeds (*British Med. Jour.*), after dilatation with the finger, extracted with the lithotomy forceps a stone from the female bladder weighing nine drachms one scruple; the circumference longitudinally was five inches; the circumference transversely was three and three-fourths inches. A rapid recovery followed without incontinence of urine.

A CASE OF EXTRAORDINARY FECUNDITY.—A. C. White, M.D., of Spring Hill, Tenn. (*Rich. and Louisville Med. Jour.*), transmits an extraordinary case of fecundity, occurring in a colored woman, aged 36 years, who has borne twenty-six children. This case was alluded to last year in the same journal, and he repeats that she had six children at single birth, all of whom are living; then followed twins eight times in succession; then triplets, which Dr. White delivered, and now a single birth. All of the children of plural births died in a few days or a few months after birth, excepting one of the triplets, which was still-born. The interval between her plural births has not been longer than 12 months.

THE SON OF THE LATE HENRY CLAY.—Theodore Clay, son of the distinguished Henry Clay, who died recently, was for forty years an inmate of the Lunatic Asylum at Lexington, Kentucky.

NEUROMA.—The term Neuroma (Tumor of Nerve), or rather *Neuromes*, was first employed by M. Odier of Geneva.

SUCCEDANEUM OF QUINIA.—M. Pavia, Professor of Chemistry in Italy, has discovered an alkaloid, which he terms *bussine*, which was extracted from the leaves and roots of boxwood. Several Italian physicians have used it in their practice, and with success, at the rate of 75 per cent. of cures.

WILLARD ASYLUM FOR THE INSANE.—The completed buildings of this new institution are located on the east bank of Seneca Lake, in the town of Ovid, Seneca county, New York, on the farm known as the farm of the "State Agricultural College," consisting of about 475 acres, lying about half a mile on the lake, running back from it one to one and a half miles. Thus located, the asylum is easy of access, two steamers passing it each way daily, and landing within fifty rods of the asylum, connecting at Geneva with the New York Central, and at Watkins with the New York and Erie Railroads.

The north and south wings, designed for the insane and their attendants, will accommodate 250 persons.

Since October 12, 1869, one hundred and forty-two insane persons, from twenty-one different poor-houses in the State, have been received into the asylum; of which, sixty-four were males, and seventy-eight females. Forty-seven were between the ages of thirty and forty; thirty-eight were between forty and fifty; twenty-one between fifty and sixty years. Eighty-eight were born in New York State and thirty-five in Ireland. Fifty were married, and eighty-eight unmarried. Forty-eight were house-workers, seventeen were farmers, and thirteen laborers. The form of mental disease is as follows:—Dementia, fifty-seven; chronic mania, sixty-three. Thirty-three per cent. were excitable and dangerous; the remainder tranquil and manageable. Ten per cent. of those admitted were found to be epileptics.

The trustees express great satisfaction and approval of the conduct of the medical superintendent, Dr. John B. Chapin, and Dr. Chas. L. Welles, the assistant physician.

HYDRARTHROSIS.—During the last fifteen years sixty-nine bonâ fide cases of hydrarthrosis have come under the observation of Dr. Louis Bauer, of St. Louis, Mo. Of these, fifty-one cases could be distinctly traced to traumatic causes.

"ONE MONKEY'S MEAT ANOTHER MONKEY'S POISON."—Some interesting experiments have been lately made in India with strychnine upon monkeys by Surgeon Ringer, Seventh Cavalry, which not only tend to show that certain species are susceptible to this poison, while others are proof against its influence, but also lend support to the prevailing impression that these animals will never eat any poisonous substance, however much disguised. A specimen of the "Chunder" monkey (*Innuus rhisus*), which would not touch fruit in which one grain of strychnine had been concealed, succumbed in an hour and a half to the influence of three grains, dissolved in water, which had been forcibly administered to it; while, on the other hand, a "lungoor" (*Presbytis entellus*), distinguished from the above species by the absence of cheek pouches, not only showed impartiality for "bitters" by readily devouring ten-grain doses both of quinine and of strychnine concealed in fruit, but also drank with much gusto some grog, in which as many grains of the latter drug had been dissolved, and is, moreover, "as well as ever at the present moment."—*Lancet.*

DEATH OF DR. JAMES COPLAND.—This celebrated London practitioner, and author of the popular *Medical Dictionary*, after a labor of thirty years, died from hæmaturia, July 12, 1870, at the ripe age of 79. Dr. Copland survived the completion of his valuable Dictionary twelve years. He was editor of the *London Medical Repository* from the year 1822 to 1835.

SYPHILIZATION.—Prof. W. Boeck, of Christiania, now in this country advocating the treatment of syphilis by the repeated inoculation of venereal matter, as proposed by M. Auzias Turenne, in 1844, believes "syphilization" acts, and acts only, through the absorption of the virus inserted in the repeated inoculations.

ANEURISM OF THE ORBIT.—The first reported instance of aneurism of the orbit is Mr. Travers' case (*Med. Chir. Trans.*) in 1809, described as "aneurism by anastomosis." Dr. Thomas Geo. Morton, of Philadelphia (*Am. Jour. Med. Sciences*), believes it was a true aneurism, or a diffuse one following upon rupture of the former. Next is Mr. Dalrymple's in 1813, which was also described as an "aneurism by anastomosis," and similar to Mr. Travers'.

VASCULAR PROTRUSION.—Thomas Geo. Morton, M.D., of Philadelphia (*Am. Jour. Med. Sciences*), has published an interesting article on "Orbital Aneurismal Disease," and adds that Mr. Nunnelly has reported no less than seven cases of orbital disease of a vascular nature, and proposed the term "*Vascular Protrusion.*"

CARRYING THE OBSTETRIC FORCEPS.—Ellerslie Wallace, M.D., Prof. of Obstetrics in Jefferson Medical College, Philadelphia (*Am. Jour. Med. Sciences*), remarks to his medical class as follows: "I deny the right of any man to attend a case of labor, unless he carries his forceps with him; and I consider that teaching erroneous which says, Go without your forceps, but *send for them* when you see the probable necessity of their use."

THE PRIORITY IN THE OPERATION OF KOLPOKLEISIS.—Dr. Nathan Bozeman, of New York (*Am. Jour. Med. Sciences*), in reply to Gustave Simon, Prof. of Surgery in the University of Heidelberg, with reference to the claim of priority in the operation of *Kolpokleisis* (transverse obliteration of the vagina), withdraws his own, made in 1867, and alludes to A. Bérard's case, published in 1845, in Dict. de Med., vol. XXX., which takes precedence. *Kolpokleisis*, in the latter case, was not less completely effected than in the first operations recorded by Prof. Simon.

GUY'S HOSPITAL, LONDON.—This old hospital, founded in 1721, has 572 beds, of which 344 are reserved for surgical cases, 216 for medical, and 12 are devoted to private cases.

ST. GEORGE'S HOSPITAL.—Dr. Reginald Thompson, Medical Register of this London hospital, reports that peroxide of hydrogen has been faithfully administered in cases of diabetes to patients admitted into this institution, and is valueless as a remedy in this disease.

THE FIRST ENTIRE EXCISION OF THE SCAPULA.—George Pollock, Esq., Surgeon to St. George's Hospital (*St. George's Hospital Reports*), publishes two cases of excision of the scapula, and attributes the first entire excision of the scapula to the late Mr. Syme. Langenbeck was the first, as his operation preceded that of the Scotch surgeon by several months.

INSANITY PRODUCED BY SPIRIT-FAITH.—Charles Elam, M.D., M.R.C.P., asserts in his "Physician's Problems," that "of the lunatics confined in asylums in the United States, there are 7,520 who have become so entirely owing to this 'spirit-faith.'"

LITHOTOMY.—The last twenty-two cases of lithotomy performed at St. Bartholomew's Hospital have been without exception successful.

THE PULSE IN PARTURITION.—In the Coombe Lying-in Hospital, out of 100 consecutive cases of parturition in which the daily state of the pulse was noted, it was found as low as 60 in 5 cases, and within the first 24 hours after delivery; it had risen to from 70 to 84 on the second day in each, and maintained this average as long as the patient tarried in hospital. In one case the pulse was as low as 56 eight hours after labor. This woman was delivered in the street, on her way to the hospital. On the second day the pulse was 72. On the seventh it was 84. This was the only case of the list in which the pulse was under 60.—*Dublin Quart. Journ. Med. Science.*

AN EPIDEMIC OF ROSEOLA PREVAILING IN CENTRAL KENTUCKY.—John D. Jackson, M.D., of Danville, Ky. (*The Rich. and Louisville Med. Journal*), gives an account of an epidemic of Roseola now prevailing in Lincoln and Mercer counties, Ky., and adds that he has not heard of a single instance in which an adult has been attacked. He has not yet seen or heard of a case in which there was a second attack, or a fresh recurrence of the eruption within a week or ten days after subsidence, as is not unfrequently the case in roseola. Its appearance in some families in which the first case would be that of one of the children who had been going to a school in which it was prevailing among the scholars, and then those who had all the while been remaining at home having it in succession, seems a strong argument in behalf of its contagiousness.

THE FIRST WRITERS ON GONORRHŒAL RHEUMATISM.—John Hunter, Schwediaur, and Th. Selle, in 1781, described this affection, and Hippocrates, in his aphorism, *Eunuchi non Laborant Podagra*, is thought to have referred to it. Then came the articles of Murray, Vegarons, 1786, of Joannis Colli, Monteggia.

NITROUS OXIDE GAS IN EXCISION OF THE MAMMA.—J. R. Begg, Surgeon to the Dundee Royal Infirmary, advocates the employment of this gas as an anæsthetic in amputation of the mamma. A writer in the *Richmond and Louisville Medical Journal* has also employed this gas in many cases of minor surgery with uniform good results.

FEMALE MEDICAL STUDENTS.—We are informed the lecturers at Surgeons' Hall, Edinburgh, have adopted the following resolutions:—"1. That it is expedient that lecturers in this medical school should be free to lecture to female as well as to male students. 2. That no restrictions be imposed upon lecturers as to the manner in which instruction is to be imparted to women."—*Med. Press & Circular.*

"NATURE" states that the University of Vienna has decided to admit women to all the advantages of its medical school, and that two French students have already availed themselves of the privilege.

CHANGES OF TEMPERATURE IN TYPHOID FEVER.—M. Garcin, of Marseilles, has published, on the authority of Professor Fabre, a series of observations of great value and importance on temperature in typhoid fever. There is, it appears, a distinct relation between the temperature and the intestinal lesion. As long as the intestinal glands are infiltrated and swollen, the thermometric rise is constant; whilst they are ulcerated, the thermometer is stationary, and is in a remarkable manner subject to peculiar changes. If the products of the ulceration are in course of elimination, the temperature is uniform. If, on the contrary, the septic products are absorbed, pass into the blood, and cause poisoning, the interstitial combustion takes on new activity, the temperature again rises, and finally the descent of the thermometer indicates the repair of the intestinal lesions.—*Med. Press & Circular.*

THE LATE EPIDEMIC IN THE PITTSFIELD FEMALE SEMINARY.—The fatal typhoid fever which prevailed, some months since, in the Pittsfield Female Seminary, Mass., was clearly traceable to a foul and neglected cesspool and privies, the air from which was conveyed through the halls of the seminary by a wretched system of ventilation.—*Mich. University Med. Journal.*

SIMPLE SYRUP AS A COLLYRIUM.—In granular lids, Dr. Lawson Tait, of London, has advocated simple syrup as a collyrium. He uses syrup, made of such strength that it does not deposit sugar; about three drachms to an ounce of water.

THE LARGEST CALCULUS ON RECORD.—A cast of the following urinary calculus was exhibited at a meeting of the Pathological Society of London, March 15, 1870. The calculus, composed of uric acid and urate of lime, weighing twenty-five ounces, and measuring ten and a half inches in its long, and eight and a half inches in its short circumference, was removed from the body of Sir Thomas Adams in 1667, after death from an accident, in the eighty-first year of his age.—*Mich. Univ. Med. Journal.*

AN ANECDOTE OF SIR SAMUEL GARTH.—This celebrated and witty physician, in the year 1700, stumbling into a Presbyterian church one Sunday, for pastime, found a pathetic preacher shedding tears over the iniquity of the earth.

"What makes the man greet?" asked Garth of a bystander.

"By my faith," was the answer, "and you too would greet if you were in this place and had so little to say."

"Come along, my dear fellow," responded Garth to his new acquaintance, "and dine with me. You are too good a fellow to be here."

SYDENHAM.—This distinguished man died in his house, in Pall Mall, London, on the 29th of December, 1689. In his last years he was a martyr to gout.

A DESCRIPTION OF THE DISCOVERER OF THE BLOOD CIRCULATION.—Aubrey says of Harvey—"He was not tall, but of the lowest stature; round-faced, olivaster (like waintscott) complexion; little eie—round, very black, full of spirit; his hair was black as a raven, but quite white twenty years before he died. I remember he was wont to drink coffee, which he and his brother Eliab did, before coffee-houses were in fashion in London. He was, as all the rest of his brothers, very cholerique; and in his younger days wore a dagger (as the fashion then was); but this doctor would be apt to draw out his dagger upon every slight occasion. He rode on horse-back with a footcloth to visit his patients, his man following on foot, as the fashion then was, was very decent, now quite discontinued."

AN UNGUENT FOR HYPOCHONDRIACAL PERSONS.—Sir Theodore Mazerno, of England, the most eminent physician of his time, and whose list of monarch-patients comprised two French and three English sovereigns, died at Chelsea, in the 82d year of his age, March 15, 1655. Like John Hunter, he was buried in the church of St. Martin's-in-the-Fields. His prescriptions show that his enlightenment was not superior to the prevailing ignorance of the period.

His sweetest compound was his "Balsam of Bats," strongly recommended as an unguent for hypochondriacal persons, into which entered adders, bats, sucking-whelps, earth-worms, hog's grease, the marrow of a stag, and the thigh-bone of an ox.

A TIME-HONORED STAFF.—The celebrated "gold-headed cane" which Radcliffe, Mead, Askew, Pitcairn, and Baillie successively bore, is preserved in the London College of Physicians, bearing the arms which those gentlemen assumed, or were entitled to.

THE PRIZE SYSTEM IN SCHOOLS.—Benjamin W. Richardson, M.D., F.R.S. (*Am. Jour. of Insanity*), alludes to this subject in his paper on "Physical Disease from Mental Strain," as follows: "I have always persistently opposed the special prize system in schools. As a teacher with large experience, and as a student, I can

recall no single instance in which noted prizemen in early youth bore away more than other youths the prizes, that is to say, the successes, of after life. I have, however, known many, many times the successful prizemen in the class the least successful afterwards, and as often have known the most ordinary man in class come out as the best man in life."

QUACKERY IN OLDEN TIME.—A successful quack by the name of Graham, established himself in a spacious mansion in the Royal Terrace, Adelphi, London, in the year 1780. The "Temple of Health," as it was usually spoken of, quickly became a place of fashionable resort, and amongst the furniture was a celestial bed, provided with costly draperies and standing on glass legs. Married couples, who slept on this couch, were sure of being blessed with a beautiful progeny. For its use £100 per night were demanded, and numerous persons of rank were foolish enough to comply with the terms.

NEW YORK TUMOR DISPENSARY is a new institution, located at 101 East 30th Street, N. Y., for the gratuitous treatment of such as are afflicted with morbid growths. J. A. Hagy, M.D., is the Attending Surgeon, and Drs. T. A. Emmet and J. C. Nott the Consulting Surgeons.

SUNSTROKE.—A writer in the *N. Y. Medical Journal* asserts that the earliest reference in literature to sunstroke is the death of Manasseh in the barley-harvest: —"The heat came upon his head, and he fell upon his bed, and died in the city of Bethulia." The earliest account of any value in English medical literature is that of Mr. Russell, of the 73d line, while in charge of the 68th at Madras, in 1834.

If the author will consult the 4th chapter of 2d Kings, of the Old Testament Scriptures, at the 18th and 19th verses, the following words relative to the son of the Shunammite woman, aged about 14 years, which are supposed by prominent divines to indicate *the first recorded case of sunstroke*, are apropos:—"And when the child was grown, it fell on a day, that he went out to his father to the reapers. And he said unto his father, My head, my head. And he said to a lad, Carry him to his mother."

THE BRITISH POPULATION.—Between 1750 and 1800, the British population rose from twenty to forty millions.

DEATH OF THE QUEEN'S SURGEON-DENTIST.—Robert Nasmyth, F.R.C.S.E., and Surgeon-Dentist to the Queen, died May 20th, æt. 78. He was a skilful surgeon, as well as dentist.

OHIO STATE MEDICAL SOCIETY.—At the late meetings of this prosperous Society, held at Cleveland, June 14th, 15th, and 16th, 1870, the following officers were elected for the ensuing year:—President, Dr. Thad. A. Reamy, of Zanesville; Secretary, Dr. W. C. Hall, of Fayetteville; Assistant Secretary, Dr. E. H. Hyatt, of Delaware; Treasurer, Dr. J. B. Thompson.

On motion of Dr. E. B. Stevens, Cincinnati was selected as the place for meeting for 1871.

SÉDILLOT.—This great surgeon of Strasburg, aged 70, has requested the Minister of War to be allowed to join the army of the Rhine as a surgeon volunteer.

PARIS MEDICAL STUDENTS.—The French Minister of War has announced that all medical students in Paris who have completed three years of study will be received with the rank of Assistant Surgeon into the military hospitals organized in the theatre of war. Above a hundred medical students have already answered to the call, and received their assignment.

THE NEW SPOUTING SPRING AT SARATOGA.—This new and favorite water is a powerful cathartic, and very agreeable as a beverage. Prof. C. F. Chandler, Ph.D., of Columbia College School of Mines, has made the following analysis, from water collected by himself personally at the fountain:—Chloride of sodium, 562.080 grains; chloride of potassium, 24.634 grains; bromide of sodium, 2.212 grains; iodide of sodium, 0.248 grains; fluoride of calcium, trace; bi-carbonate of lithia, 7.004 grains; bi-carbonate of soda, 71.232 grains; bi-carbonate of magnesia, 149.343 grains; bi-carbonate of lime, 170.392 grains; bi-carbonate of strontia, 0.425 grains; bi-carbonate of baryta, 2.014 grains; bi-carbonate of iron, 0.979 grains; sulphate of potassa, 0.318 grains; phosphate of soda, trace; bi-borate of soda, trace; alumina, trace; silica, 0.665 grains; organic matter, trace. Total solid contents, 991.546. Carbonic acid gas in U. S. gal., 454.082 cub. in.; density, 1.011; temperature, 46° Fah. It spouts day and night, to the height of twenty feet, thirty gallons every minute, through an inch nozzle, under the pressure of its own carbonic acid gas. This spring is situated two miles south of the village of Saratoga.

ACADEMY OF SCIENCES: PRIZES FOR 1870 ADJUDICATED.—The Academy held a public sitting, July 11, for the announcement of the names of those to whom the prizes for 1870 had been adjudicated. The President, Prof. Claude Bernard, announced the following prizes:

The *Prix de Statistique* was awarded to Dr. Chenu, for his great work entitled *Statistique Medico-Chirurgicale de la Campagne d'Italie en* 1859 *et* 1860.

The *Prix de Médecine et de Chirurgie* was not awarded this year. The subject proposed was the "Application of Electricity to Therapeutics." Though the prize was not given to any one, medals were given to three meritorious physicians—viz., Drs. Legros, Onimus, and Cyron.

The *Prix de Physiologie Experimentale* was awarded to M. Famitzin, for his researches into the influence of light upon the nutrition of plants. An honorable mention, with a gift of 60 francs, was also decreed to MM. Léon, Tripier, and Arloing, for their researches on the cutaneous nerves.

The *Prix Bréant* (5,000 francs) was given to Dr. Fauvel, for his work on the "Etiology and Prophylaxis of Cholera." Twenty-five authors sent in works in candidature for this prize.

The *Prix de Médecine et de Chirurgie de la Fondation Montyon* was divided among three medical gentlemen. Five doctors were honorably mentioned in connection with this prize.—*British Med. Journal.*

INFANTILE CHOLERA IN PARIS.—This disease—that is to say, the summer diarrhœa of infants—is very prevalent in Paris.

ON CERTAIN POINTS CONNECTED WITH

THE HISTOLOGY OF MINUTE BLOOD-VESSELS.

BEING A REPORT TO

SURGEON-GENERAL J. K. BARNES, U. S. A.,

By J. J. WOODWARD, M.D.,

ASSIST. SURG. AND BREVET LIEUT.-COL., U. S. A., ETC., ETC.

BREVET MAJOR-GENERAL J. K. BARNES, SURGEON-GENERAL, U. S. ARMY.—*General*: Having recently been occupied in the critical examination of certain preparations, in the Microscopical Section of the Museum, illustrative of the minute anatomy of the blood-vessels, I have thought that some of them threw so much light on certain points involved in the recent discussions with regard to the doctrine of inflammation, that a short account of them would be of interest, and might perhaps do good service, in connection with the appreciation of the conflicting statements which have appeared in the medical journals since the publication of the paper of Dr. J. Cohnheim,* on inflammation and suppuration.

Perhaps the observations of Cohnheim must fairly be regarded as elaborations of the previous experiments of Dr. Augustus Waller, but certainly they produced an impression upon the medical world far beyond that made by the papers in the Philosophical Magazine,† and more or less complete accounts of the conclusions arrived at by the distinguished Berlin observer have continued to appear, from time to time, in both foreign and American medical journals, ever since the publication of his paper in 1867.

Recently protests against these conclusions have appeared in various quarters, among which particular reference may be made to the paper of Prof. Koloman Balogh, of Pesth, published in 1869,‡ and that of Dr. V. Feltz, of Strasbourg, in 1870.§ Both these authors have failed to see the white blood corpuscles pass through the coats of the small vessels in the manner described by Cohnheim, and deny the existence of stomata, between the cells of the vascular epithelium, large enough to permit such a wandering to occur.

It is well known to you, General, that after I had perused Cohnheim's paper I procured a number of frogs, and having on hand a small quantity of Wourara, the gift of my friend Dr. S. Weir Mitchell, of Philadelphia, I carefully repeated many of the experiments described. I received the impression from what I saw that Cohnheim was a most conscientious observer, who had described as faithfully as possible the impressions made upon him. Certainly the results I obtained, by following his methods of producing inflammation in the cornea and mesentery of frogs, could be described in his very language without drawing upon the imagination. Nevertheless my other duties did not leave me sufficient time for an exhaustive research in this difficult domain, and it is far from my present purpose to enter into a critical discussion of the subject. It is simply my desire to offer a brief description, illustrated by Photo-micrographs, of certain preparations in the Microscopical Section of the Museum, which bear upon some of the points involved, and thus to contribute what is in my power towards the important object of arriving at certainty with regard to the facts on which our future theories of inflammation are to rest.

Most of the preparations here referred to are examples of the results attainable by staining the tissues with a dilute solution of the nitrate of silver. This reagent has been employed for various histological purposes during the last ten years, and has attracted attention especially in connection with the cornea, the various forms of connective tissue, the ultimate branches of the lymphatics and the boundaries of the cells which constitute epithelial surfaces. General attention was first drawn to its use by Dr. F. von Recklinghausen, of Berlin, in 1860,* and further particulars were contributed during 1861, by Prof. His, of Basil,† who would appear to have already employed the reagent for several years. In 1862 Von Recklinghausen published his work on the lymphatics,‡ which contains a detailed account of many elaborate experiments with regard to the action of silver solutions on the tissues, and in 1863 Dr. Ernst Oedmanson, of Stockholm,§ gave a description of their behavior when applied to epithelial surfaces, and described and figured the so-called stomata which play so important a part in the theory of Cohnheim. During 1865 and 1866 the epithelium of the capillary blood-vessels, as shown by silver, was described by several observers, among whom Dr. N. Chrzonszczewsky, of Charkow,‖ may be particularly mentioned.

The perusal of these papers led me to make a number of experiments myself, and to have others made by my assistants at the Museum, the results of which are now to be described.

If a dilute solution of nitrate of silver is brushed over a clean epithelial surface taken from a recently killed animal, and the tissue after washing with distilled water is exposed for a short time to the action of sunlight, it will be found on microscopical examination that a brownish black precipitate of silver has been produced at the boundaries of the epithelial cells, while the cells themselves are comparatively but little stained, or, if the manipulation has been carefully conducted, are not stained at all. For this purpose I have most frequently employed, at the Museum, a solution made by dissolving one part of crystallized nitrate of silver in four hundred parts of distilled water, but considerable variation on either side of this strength does not much

modify the result, provided the solution is well washed off before the tissue is exposed to the light.

If the same solution is injected into the blood-vessels, the lining epithelium is handsomely mapped out in all those membranous and superficial parts in which a ready exposure to the action of light is practicable, and although in the parenchymatous organs, such as the liver, the spleen, the kidneys, etc., the juices of the tissues are apt to interfere with the reaction, yet even here occasional success may be attained. In practice it is often found advantageous to combine the silver solution, intended for injection, with a certain amount of gelatine, by which the blood-vessels are kept handsomely distended and the beauty of the preparation is much increased. This plan was proposed by Chrzonszczewsky in the paper already quoted. His formula, which I have found to work well, is as follows: Half an ounce of fine gelatine is dissolved in four ounces of distilled water, and to this is added a solution of one scruple of nitrate of silver in two fluid drachms of distilled water. After injecting with this fluid, the tissue is exposed to the light precisely as after the use of the simple silver solution.

There are preserved in the Microscopical Section of the Museum a number of silver stainings in which the epithelium has been thus mapped out on the skin, the peritoneum, the lymphatic-sacs of frogs, and the blood-vessels. These preparations, after the action of the silver, have been mounted in Canada balsam, with or without the previous staining of the nuclei with carmine. The detailed steps of the process may prove useful to some readers. The silver staining having been successfully accomplished, the nuclei are tinted preferably by the solution of carmine in borax, described by Thiersch in his work on epithelial cancer.* It is prepared as follows: Four parts of borax are dissolved in fifty-six parts of distilled water and one part of carmine added to the solution; one volume of this fluid is mixed with two volumes of absolute alcohol, and after crystals have formed the mixture is filtered. The filtrate may be used for staining, but if the crystals of carmine and borax which remain on the filter are dissolved in a small quantity of distilled water, I find the solution thus obtained answers a still better purpose. The portion of tissue to be studied is soaked in this solution until colored deep red. It is afterwards treated with a saturated solution of oxalic acid in alcohol, by which all color is gradually removed except from the nuclei. So soon as this is accomplished the piece is to be carefully washed in alcohol, then soaked in absolute alcohol, and finally mounted in a solution of dried Canada balsam in chloroform or benzole. The treatment by oxalic acid, subsequently to the action of the carmine-borax solution, has the additional effect of altering the purplish-red color, derived from that fluid, to the brilliant hue obtained by the use of the ammoniacal solution of carmine ordinarily employed in histology. The latter has the disadvantage of being apt to dissolve out the previously produced silver staining, an annoyance completely avoided by the carmine-borax solution.

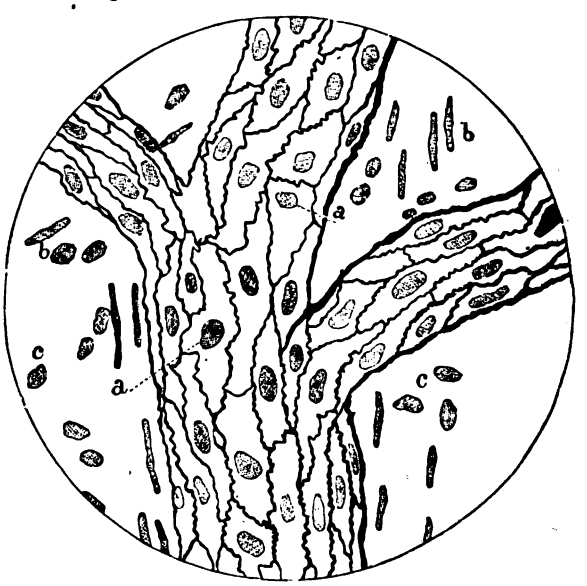
Preparations carefully made by the above process closely resemble the fresh tissues, as they appear after staining if immersed in glycerine or syrup; they are somewhat more transparent, but not inconveniently so, and possess the great advantage of keeping unchanged for an indefinite period of time.

After these preliminary remarks, I proceed at once to the description of the photographs.

I. Photograph representing several venous radicles uniting to form a small vein, in the muscular coat of the urinary bladder of the frog. Negative No. 102, New Series. From preparation No. 3,378, Microscopical Section. Magnified 400 diameters by Wales's ¼th objective, illuminated by the Magnesium lamp. The preparation was made by Dr. J. C. W. Kennon.

The principal venous trunk represented in this photograph is 1-400th of an inch in diameter. It is formed by the union of three smaller radicles, of which that on the left hand is much out of focus. Another smaller radicle, also much out of focus, joins the trunk on the left, near the bottom of the picture. The walls of the venous trunk, and of those of its branches which are in focus, are plainly seen to be formed of somewhat irregular epithelial cells, which vary in shape and size, averaging 1-500th of an inch in length and 1-2200th in breadth. The boundary of each cell is indicated by a zigzag black line. In each of the cells which is accurately in focus, a smooth, oval nucleus, 1-2800th of an inch in length, is visible. In examining the original preparation, by changes in the fine adjustment of the microscope, similar nuclei can be seen in each of the epithelial cells. These nuclei, being brilliantly stained with carmine, contrast sharply with the black cell-boundaries resulting from the silver imbibition. By a still further alteration of the fine adjustment, the cells and nuclei of the opposite side of the vein are brought into view.

In the tissue external to the vein, two kinds of nuclei are shown in the photograph. The first are narrow and elongated, averaging about 1-1500th of an inch in length and 1-9000th in breadth. These are the

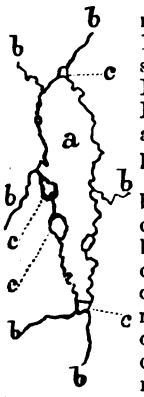


nuclei of the fibre-cells of the muscular coat of the bladder. The fibre-cells themselves are not shown in carmine stainings, but are readily demonstrated in fresh preparations by the action of solutions of osmic acid, or of chloride of gold. Indications of the muscular bands formed by the union of these fibre-cells are, however, seen in the photograph, particularly on each side of the principal venous trunk. The second variety of nuclei are oval, about 1-3000th of an inch long, and belong to the connective tissue of the bladder. The cells in which these nuclei lie are not seen, the action of the carmine being limited to the nuclei. They can, however, readily be demonstrated in fresh preparations by gold-chloride and some other reagents. The cut

* Der Epithelialkrebs. Leipzic, 1865, S. 92.

represents the outlines of a portion of the photograph; a, a, are the nuclei of the vascular epithelium; b, b, the nuclei of the muscular fibre-cells; c, c, those of the connective tissue.

II. Photograph representing a small vein from another portion of the same preparation. Negative No. 195, New Series. Magnified 1,000 diameters by Powell and Lealand's immersion 1-16th objective, illuminated by the Magnesium lamp. One of the epithelial cells near the centre of the vessel is particularly well defined, and shows its nucleus handsomely; the adjacent cells, not lying in the same plane, are many of them partly out of focus, but their boundaries can readily be traced, and the nuclei of several of them are well defined. Four black spots, seen in the course of the vessel, are blood corpuscles much out of focus.



III. Photograph representing the stomata between the epithelial cells of a vein 1-50th of an inch in diameter in the mesentery of the frog. Negative No. 40, New Series. From preparation No. 3,276, Microscopical Section. Magnified 400 diameters by Wales's ⅛th objective. The preparation was made by myself.

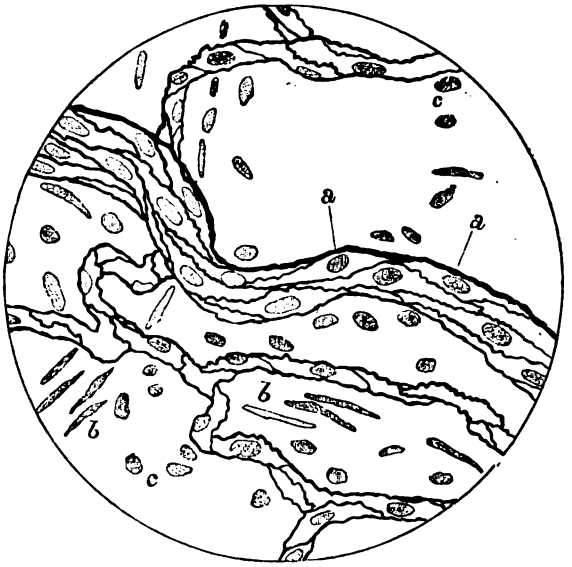
Owing to the curved form of the vein, but a small portion of its surface is in focus. In this portion the silver stained boundaries of several of the epithelial cells of the vein are visible, and display in their course certain remarkable forms, which may be compared to the Wormian bones of the cranial sutures. These are the so-called stomata. They are irregularly rounded in form, and vary from the 1-10,000th to the 1-4000th of an inch in long diameter. Those shown in the photograph present a clear central space, bounded by a sharp, black outline, which is sometimes even thicker than the boundaries of the cells themselves. The nuclei of the epithelial cells are not shown. The cut exhibits one of these cells, a, with portions of the boundaries of adjacent cells, b, b, b, and the stomata, c, c, c.

IV. Photograph representing the stomata between the epithelial cells of a vein, 1-100th of an inch in diameter, in the mesentery of the frog. Negative No. 224, New Series. From preparation No. 3,062. Microscopical Section. Magnified 400 diameters by Wales's ⅛th objective. The preparation was made by Dr. Kennon.

The vein having collapsed, the epithelial cells of the lower wall come into focus in places, and so somewhat complicate the representation. The stomata are abundantly present, but none of them equal in size the largest shown in the last photograph; in several places, moreover, black spots, similar to the other stomata in shape and size, may be observed in the cell boundaries.

V. Photograph representing the stomata of a vein, 1-1000th of an inch in diameter, in the mesentery of the frog. Negative No. 194, New Series. From preparation No. 3,276. Microscopical Section. Magnified 400 diameters by Wales's ⅛th objective, illuminated by the Magnesium lamp. The small vein represented comes well into view, while the nuclei of the surrounding tissue are seen out of focus on each side of it. Several of the stomata present clear centres, while others are black and opaque throughout; they average 1-10000th of an inch in diameter.

VI. Photograph representing a minute artery, with part of the adjoining net-work of capillaries, from the muscular coat of the urinary bladder of the frog. Negative No. 220, New Series. From preparation No. 3,378, Microscopical Section. Magnified 400 diameters by Wales's ⅛th objective. The field is crossed by a small artery, 1-1700th of an inch in diameter. Its epithelial cells are longer in proportion to their width than those of the veins. They average 1-400th of an inch in length, and have nuclei similar to those of the venous epithelium. Wherever the capillaries come into focus the epithelium of their walls is also plainly shown. In the intervascular spaces the nuclei of the muscle and connective tissue appear as in the first photograph. The cut presents an outline of a part of the picture; a, a, are the nuclei of the vascular epithelium; b, b, those of the muscle; c, c, those of the connective tissue.



VII. Photograph representing a portion of the view presented by the last picture. Negative No. 223, New Series. Magnified 1,000 diameters by Powell and Lealand's immersion 1-16th objective. The spindle-shaped forms of the epithelial cells of the arteries and the characters of their nuclei are plainly shown.

VIII. Photograph representing a small artery in the mesentery of the frog. Negative No. 184, New Series. From preparation No. 3,267, Microscopical Section. Magnified 500 diameters by Wales's ⅛th objective, illuminated by the Calcium light. The preparation was made by myself. The artery shown measures 1-280th of an inch in diameter. It is marked by both transverse and longitudinal silver lines. The former are exterior to the latter, as is readily demonstrated in the preparation by the use of the fine adjustment. The longitudinal lines belong to the epithelium, while the transverse markings indicate the boundaries of the circular fibre-cells of the muscular coat, which are usually mapped out in this manner in arteries of moderate size, the silver solution reaching them by imbibition. The epithelial cells of arteries of this size are narrower in proportion to their length than those of smaller twigs, such as that shown in the last two photographs. In the photograph it is somewhat difficult, in many places, to make out their boundaries, as the margins of the cells of the opposite wall come into focus and complicate the appearance. In the study of the original preparation this difficulty is readily overcome by manipulating the fine adjustment. On each side of the artery the numerous nuclei of the surrounding tissue come more or less distinctly into view.

IX. Photograph representing the epithelium of a

capillary, in the muscular coat of the urinary bladder of the frog. Negative No. 216, New Series. From preparation No. 3,378, Microscopical Section. Magnified 1,000 diameters by Powell and Lealand's immersion 1-16th objective, illuminated by the Calcium light. The capillary which crosses the centre of the field measures 1-2300th of an inch in diameter. The epithelial cells are narrower in proportion to their length than those of the veins. Their nuclei are quite similar to those of the venous epithelium.

The foregoing description of individual photographs will serve to give a correct idea of the epithelium lining the small arteries, veins, and capillaries, as shown in a considerable number of preparations preserved in the Museum, and as observed by me many times in tissues extemporaneously prepared. Both Balogh and Feltz would seem to have been singularly unfortunate in their silver stainings, for they describe the appearances produced as irregular and contradictory. Balogh explains the black lines he occasionally saw in the vessels after silver injections as due to the precipitate of silver occurring preferably on folds in the lining membrane, caused by the irregular shrinkage of the vessel produced by the silver injection, an error readily corrected by combining gelatine with the solution of silver injected; the vessels are thus equably and smoothly distended, yet the epithelium appears mapped out as usual.

Feltz asserts that if a solution of silver be allowed to dry in the light on a collodium film, irregular black lines are produced, quite like those observed after its action on organic membranes. I myself have examined the irregular figures produced by this experiment, and cannot conceive how any one accustomed to the precise study of organic forms can see any similarity between them and the definite outlines produced by the action of silver solutions on epithelial surfaces.

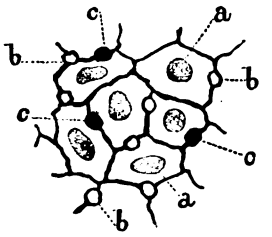
Besides the preparations exhibiting the vascular epithelium which have been described, the Museum possesses, as I have already mentioned, a number in which the epithelium of the skin, of the lymph-sacs of frogs, of the peritonæum and of other surfaces, are mapped out by silver staining, and the reagent is continually employed by myself and my assistants in the investigations of such surfaces. It is impossible for any one who has had such opportunities for observation, to avoid being struck by the fact that the outlines obtained have a definite form and character for each tissue. It is true that the silver staining does not succeed as frequently as carmine staining does, that its use requires more skill, and that failures are more frequent. Sometimes, too much action takes place and everything is obscured by the black precipitate produced; sometimes either because the tissues are not fresh, or the light not sufficient, or from some unexplained reason, the solution does not act at all; but the forms above described as characteristic of the arteries are never observed in the veins, never do the outlines produced on the surface of the skin resemble those seen on the peritonæum, in the lymph-sacs, or in the vessels; each membrane permits only the formation of its own characteristic outlines, never of those belonging to another tissue; moreover, in all cases where it is possible to observe the shape of the epithelial cells without the use of reagents, or to isolate them, the forms thus ascertained correspond precisely with those mapped out by the silver solution, and when, after the action of silver, carmine staining is resorted to, the nuclei thus made visible correspond in position to the places they ought to occupy, if in fact the silver had mapped out the cell-boundaries, as I certainly believe it does. Whether the discoloration is in the cell-wall, or in the cement or matrix by which the adjacent cells are held together, is a more difficult question, and one into which I do not propose to enter at the present time. It is enough for the purposes of this paper that the peripheries of the cells, or the substance just external to them, exhibit a much more speedy and intense reaction with the nitrate than the cell contents do, and must therefore differ more or less from these in composition.

Having arrived at this conclusion with regard to the general interpretation of the action of silver on epithelial surfaces, the question of the true meaning of the so-called stomata next demands consideration. They are to be observed most abundantly, as may be inferred from the photographs described, in veins of moderate size. I have found them largest and most numerous in veins 1-50th of an inch in diameter, or even larger, and they become smaller and rarer in smaller branches. They are comparatively infrequent in the capillaries and still more so in the small arteries; the Museum, however, possesses preparations showing them in both. I have moreover concluded from my own observations that in number and size they vary in vessels of the same dimensions in different parts of the body. Thus, for example, in the veins of the mesentery of the frog they are larger and more abundant than in veins of the like dimensions in the urinary bladder of the same animal.

In figure they are rounded, oval or oblong. I have measured them as large as 1-4000th of an inch in diameter, but smaller ones 1-5000th to 1-6000th of an inch are more common, and the smallest and most frequent do not exceed 1-10,000th of an inch. Sometimes they present clear centres sharply mapped out by black boundaries, sometimes forms of the same size and character are opaque and black throughout, and this has been interpreted as due to variations in the composition of the fluid by which the opening is occupied, which sometimes precipitates the silver solution while at other times it does not, and the action is limited to the solid margins of the pore. They are almost invariably found in the marginal line between adjacent epithelial cells, and the rare cases in which I have observed them apparently in the cells themselves, are probably to be explained by the adjacent margins having from some cause escaped the influence of the silver salt. From my study of these peculiar inter-cellular forms, I am inclined to regard with favor the opinion that they are actual openings in the epithelial layer. It may aid others in arriving at a conclusion on the subject, if I here present a photograph of the stomata in the external epithelium of the skin of the frog through which, as is well known, a rapid transudation of liquid habitually occurs.

X. Photograph representing a silver staining of the external epithelium of the frog's skin. Negative No. 22, New Series. From preparation 3,036, Microscopical Section. Magnified 400 diameters by Wales's ⅛th. The preparation was made by myself. The epithelium of this surface consists of a number of layers, and the silver has penetrated in different portions of the skin to various depths. In the photograph the epithelial cells of the upper surface are sharply mapped out, while the boundaries of the cells of several of the deeper layers are seen out of focus beyond. The cells are hexagonal in shape, and average 1-1300th of an inch in diameter. Many of the nuclei have been somewhat tinted by the silver, a circumstance which is not unfrequent if the silver action is intense. In the boundaries of the epithelial cells may be seen very many little rings, with black margins and clear centres, averaging 1-5000th of an inch in diameter, and also many similar forms, of the

same size and occupying like positions, which are quite black and opaque throughout. In some parts of the preparation from which the photograph was taken, almost all the rings are black and opaque, while in other portions almost all present clear centres. The view which regards these rings as true pores certainly appears to me to require fewer suppositions than any other. The cut represents an outline of a portion of this photograph; a, a, the nuclei of the epithelial cells; b, b, the stomata; c, c, stomata which have become black and opaque throughout. It has been urged, however, by Balogh, that even if the stomata described in the vascular epithelium are admitted as such, they are not large enough to permit the passage of the white blood corpuscles, which, as is well known, average about 1-3000th of an inch in diameter. But even if we discard the supposition that the pores may be stretched open and made larger by the distended condition of the vessels of inflamed parts, there appears to me no difficulty in understanding how a white corpuscle might pass through the smallest of the stomata I have described. An opening 1-10,000th of an inch in diameter is only a little less than one-third the average diameter of the white corpuscles, and any one who has seen the extraordinary modifications of form which the e little masses of protoplasm undergo in the course of their so-called "amœboid movements," would readily credit their capability of passing through such apertures. As the amœboid movement does not occur in the white corpuscles while rolled along in the torrent of the circulation, but only when the movement of the blood is arrested more or less completely, the fact that large numbers of white corpuscles do not habitually pass through the vascular walls into the tissues will not militate against the notion of patulous orifices. That a passage of the white blood corpuscles through the vascular walls does actually occur, is shown by the next picture.



XI. Photograph representing white corpuscles in various phases of the amœboid movement, in the external coat of a small vein of the muscular coat of the stomach of a mare. Negative No. 46, New Series. From preparation No. 3,382, Microscopical Section. Magnified 400 diameters by Wales's ⅛th objective. The preparation was made by Dr. E. M. Schæffer.

This preparation is one of a number of sections made from the stomach of a mare dead of gastro-enteritis. In these sections, which are stained with carmine and mounted in Canada balsam after the method described in the early portion of this paper, it was found that many of the small veins of the sub-peritoneal connective tissue and of the muscular coat were surrounded by white corpuscles fixed in all stages of the amœboid movement. In a number of places where the sections pass transversely through the veins, the white corpuscles can be observed in the interior of the vein, and in the vascular walls as well as in the adjacent tissue. The series of preparations gives a satisfactory demonstration of the wandering of the white corpuscles. I have made efforts to preserve the frog's mesentery permanently, in a number of the cases in which I have observed the same process in that membrane, but hitherto without success.

It will be seen from the foregoing details that, so far as the structure of the vascular walls and the passage of the white corpuscles through them are concerned, the facts appear to be on the side of Cohnheim. How then with regard to the doctrine of inflammation which he builds upon these facts and upon his corneal studies? Does the creeping out of the white corpuscles constitute the essence of the inflammatory process? Do these little movable masses of living protoplasm furnish the germs for the elements of new formations? Have pus corpuscles no other origin? Are the processes which go on in the cells of the inflamed tissue purely passive, mere phenomena of retrograde metamorphosis?

I find the evidence insufficient as yet to afford satisfactory answers to such questions. The observations made by Cohnheim on the connective tissue corpuscles of the tongue of the frog are not conclusive in themselves, and Stricker's studies on the same subject* show the necessity of further labor in this direction before the possible multiplication of these elements in inflammation can be denied. As to the doctrine that the white corpuscles, after their escape from the blood-vessels, are transformed into the elements of normal or pathological tissues, the facts hitherto brought forward can scarcely be said to do more than raise it to the rank of an ingenious hypothesis. The actual steps of this transformation, if it does occur, have yet to be observed.

In conclusion, I may remark that, as the preparations referred to in this paper form a portion of the Microscopical Collection of the Museum, they can be examined by any professional microscopist who may visit that institution.

The photographs which accompany this paper were prepared by myself in accordance with the method described on former occasions.

I have the honor to be, General, very respectfully, your obedient servant,

J. J. WOODWARD,

Assistant Surgeon and Brevet Lieutenant-Colonel, U. S. Army, in charge of the Record and Pension Division, and of the Medical, Microscopical and Comparative Anatomy Sections of the Army Medical Museum.

THE LAW IN REFERENCE TO THE SALE OF POISONS BY DRUGGISTS.

BY FRANCIS TILLOU, ESQ.,

COUNSELLOR-AT-LAW.

THE sale of poison by druggists is regulated in the State of New York by statute.

By the Revised Statutes, vol. 2, page 649, sec. 23, it is enacted that "Every apothecary, druggist, or other person who shall sell and deliver any arsenic, corrosive sublimate, prussic acid, or any other substance or liquid usually denominated poisonous, without having the word 'poison' written or printed upon a label attached to the phial, box, or parcel in which the same is sold, or who shall sell and deliver any tartar emetic without having the true name thereof written or printed upon a label attached to the phial, box, or parcel containing the same, shall upon conviction be adjudged guilty of a misdemeanor, and shall be punished by a fine not exceeding one hundred dollars."

By an act to regulate the sale of poisons, chapter 442 of the laws of 1860, passed April 16, 1860, it was enacted by the first section of said act, that no person should sell or give any poison or poisonous substance, without recording in a book to

* Studien aus dem Institute für Experimentelle Pathologie in Wien aus dem Jahre 1869. Wien, 1870.

be kept for that purpose, the name of the person receiving said poison, his or her residence (together with the name and residence of some person as witness to such sale), excepting upon the written order or prescription of some regularly authorized practising physician, whose name must be attached to such order. Such book shall be kept open for inspection."

But by an act passed 1862, chapter 273 of the session laws of 1862, the above first section of the act of 1860 was amended by leaving out the requisition for the name of a witness to the sale.

By the second section of the act of 1860, it is further enacted that no person shall sell, give, or dispose of any poison or poisonous substance except upon the order or prescription of a regularly authorized practising physician, without attaching to the phial, box, or parcel containing such poisonous substance a label with the name and residence of such person and the word "poison" all printed upon it with *red ink*, together with the name of such poison written or printed thereon in plain and legible characters.

By the third section of the act of 1860, it was further enacted, "That the above provisions should apply to the following poisonous substances, excepting when sold in wholesale quantities of one pound or over, viz.: arsenic and its various preparations, oxalic acid, corrosive sublimate, chloroform, sugar of lead, tartar emetic, opium and its preparations, oil of bitter almonds, cyanurets of potassium, mercury, silver, and zinc, deadly nightshade, henbane, poison hemlock, prussic acid, aconite and its various preparations, atropia and its salts, cantharides, croton oil, daturia and its salts, delphinea and its salts, digitalis and its preparatious, nux vomica and its preparations, elaterium, ergot and its preparations, veratria and its salts, cannabis and its preparations."

But by the amendatory act of 1862 this third section of the act of 1860 was repealed.

By the fourth section of said act of 1860, it is enacted that any person infringing any of the provisions of said act shall, upon conviction, be deemed guilty of a misdemeanor, and shall be punished by a fine not exceeding fifty dollars.

By the fifth section of said act of 1860, it is further enacted that said act shall *only* apply to incorporated cities and villages having a population of one thousand inhabitants and upwards in this State.

By chapter 478 of the laws of 1869, an act regulating the preparation of medical prescriptions was passed May 1, 1869.

By the first section of this act of 1869, it is enacted that no person employed or in attendance at any drug store or apothecary shop shall prepare a medical prescription, unless he has served two years' apprenticeship in a drug store, or is a graduate of a medical college or a college of pharmacy, except under the direct supervision of some person possessing some one of the before-mentioned qualifications; nor shall any one having permanent charge as proprietor or otherwise of any store at which drugs are sold by retail, or at which medical prescriptions are put up for sale or use, permit the putting up or preparation thereof therein by any person, unless such person has served two years as apprentice in a retail drug store, or is a graduate of a medical college or a college of pharmacy.

And by the second section of the same act, it is provided that any person violating the provisions of said act shall be guilty of a misdemeanor, and shall be punished by a fine not exceeding one hundred dollars, or by imprisonment not to exceed six months in the county jail; and in case of death ensuing from such violation, the person offending shall be deemed guilty of a felony, and be punished by a fine not less than one thousand dollars, nor more than five thousand dollars, or by imprisonment in State prison for a term of not less than two years, nor more than four years, or by both fine and imprisonment, in the discretion of the court.

By statute every man who by his culpable negligence causes the death of another, although without any intent to kill, is guilty of manslaughter. (2 R. S. 662, sec. 19.)

The foregoing seem to be all the existing statutory provisions on the subject.

A druggist who negligently sells a poison, labelled as a harmless drug, and thereby causes the death of a person to whom it is administered, is guilty of manslaughter.

So highly does the law value human life that it admits of no justification wherever life has been lost, and the carelessness or negligence of one person has contributed to the death of another.

And this rule applies not only when the death of one is occasioned by the negligent act of another, but where it is caused by the negligent omission of a duty to that other.

Besides the penalties imposed by statute, there is also a common law liability of the druggist for damages sustained by his negligence.

All persons who deal with deadly poisons are held to a strict accountability for their use.

The highest degree of care known amongst practical men must be used to prevent injury from the use of such poisons.

And one who sells poison labelled as an innocent drug is liable in damages to any person injured thereby, no matter through how many hands it may have passed.

A druggist is undoubtedly held to a special degree of responsibility for the erroneous use of poisons corresponding with his superior knowledge of the business.

Affixing a false label to a poison, and sending it into market in that condition so as thereby to mislead others and endanger human life, is an unlawful act for which the party guilty of the act is responsible, whether he did it wilfully or negligently, and to entitle the aggrieved party to his action in such case no privity is necessary except such as is created by the unlawful act and consequential injury. Privity of contract in such case is out of the question. For a duty violated by a druggist giving a false label is a duty not created by contract, but by law, every one being under an obligation to abstain from acts tending naturally and probably to endanger human life.

The injury is not rendered too remote to sustain a recovery because separated from the unlawful act by intervening events, however numerous or of whatever kind, provided they are the natural and probable consequences of the act.

And when the unlawful act is in its nature likely to produce the events which follow, as, for instance, a patient taking a poison instead of some harmless or different prescription than that intended, by reason of a false label of a druggist, the author of it may be treated as having caused the succeeding events, though they consisted of the acts of third persons. For the false label is a continuing authority or direction by the druggist for the use of the poison, and he is bound to indemnify against the acts which it was likely to cause when sold in that condition.

The foregoing propositions seem to be fully sustained by the case of Thomas *vs.* Winchester, in the Court of Appeals.

That was an action brought to recover damages for negligently putting up, labelling, and selling as and for

the "Extract of Dandelion" a jar of the "Extract of Belladonna," by means of which the plaintiff's wife, Mrs. Thomas, being sick, a dose of dandelion was prescribed by a physician, and a portion of the contents of the jar of belladonna was administered as and for the extract of dandelion, &c.

The facts of the case, briefly, were as follows:—

The defendant, Winchester, was engaged at 108 John street, New York, in the manufacture and sale of certain vegetable extracts for medicinal purposes, and in the purchase and sale of others.

The extracts manufactured by him were put up in jars for sale, and those he purchased were put up by him in like manner.

The jars containing extracts manufactured by himself, and those containing extracts purchased by him from others, were labelled alike—both were labelled as "prepared by A. Gilbert," a person in the employ of defendant.

The jar in question was labelled "½ *lb. Dandelion, prepared by A. Gilbert, No.* 108 *John st., N. Y.;*" and in fact contained belladonna, and not dandelion.

The jar was sold by defendant to a wholesale druggist in New York, as and for the extract of dandelion. Dr. Foord, a physician and druggist at Cazenovia, Madison county, N. Y., purchased the article from the New York druggist, as and for the extract of dandelion.

Mrs. Thomas being ill, her physician prescribed a dose of dandelion. Her husband purchased what was believed to be the medicine prescribed, at the store of Dr. Foord. The medicine was taken from the jar in question and administered to Mrs. Thomas, who was thereby made dangerously ill, and the action was brought against Winchester and Gilbert to recover damages.

It appeared that the extract in the jar in question was not manufactured by defendant himself, but was purchased by him from another manufacturer or dealer, but labelled with Gilbert's labels, which labels were paid for by Winchester, and used in his business with his knowledge and assent.

It was objected, among other questions, that the action could not be sustained, as the defendant was the remote vendor of the article in question, and there was no connection, transaction, or privity between defendant and the plaintiff.

A verdict was rendered against the defendant Winchester; the defendant Gilbert being acquitted by the direction of the Court.

The defendant Winchester appealed to Court of Appeals, and it was there held that a dealer in drugs and medicines, who carelessly labels a deadly poison as a harmless medicine, and sends it so labelled into market, is liable *to all persons* who, without fault on their part, are injured by using it as such medicine in consequence of the false label. That the liability of the dealer, in such case, arises not out of any contract or direct privity between him and the person injured, but out of the duty which the law imposes upon him to avoid acts in their nature dangerous to the lives of others. He is liable, therefore, though the poisonous drug with such label may have passed through many intermediate sales before it reaches the hands of the person injured. That where such negligent act is done by an agent, the principal is liable for the injury caused thereby.

Although the defendant Gilbert was acquitted by the jury under direction of the Court, and judgment rendered against the defendant Winchester alone for damages, Judge Ruggles, in delivering the opinion of the Court of Appeals, said that "Gilbert, the defendant's agent, would have been punishable for manslaughter, if Mrs. Thomas had died in consequence of taking the falsely labelled medicine."

2 R. S., 662, § 17.
Tessymond's Case.
1 Lewin's Crown Cases, 169.
Regina *vs.* Swindall.
2 Car. & Ker., 232.

"Although the defendant Winchester may not be answerable criminally for the negligence of his agent, there can be no doubt of his liability in a civil action, in which the act of the agent is to be regarded as the act of the principal."

See the case fully reported in 6 New York (2 Selden) Reports, page 397, and the numerous authorities there cited and referred to.

The law regulating the sale of poison by druggists might be amended in this respect:—

Druggists should be required, in addition to the label of poison and the name of the poison, to name also the antidote to such poison, and give brief directions for administering the antidote. This should be printed or written plainly and legibly, so that in cases of poison being taken by accident or design, an antidote could be quickly administered without the delay of getting a physician; and no doubt many lives could thereby be saved.

The law of 1860 seems to be defective in limiting its application to incorporated cities and villages having a population of one thousand inhabitants and upwards.

It might with advantage be made general in its application throughout the State.

NEW YORK, Sept. 1, 1870.

Original Lectures.

THE PRACTICAL VALUE OF CERTAIN NEW TESTS FOR ALBUMEN.

Read before the New York Medical Journal Association.

BY WM. B. LEWIS, M.D.,

LECTURER ON RENAL AND URINARY DISEASES IN THE UNIVERSITY MEDICAL COLLEGE; MICROSCOPIST TO CHARITY HOSPITAL, ETC.

IT is an observation not uncommonly made that there are fashions in medicine as well as in dress. May it not be stated with equal truth that, especially in the experimental departments of our profession, discoveries are frequently made and quoted as new which really are venerable with years? We would not too severely criticise such reappearances of old truths, if truths they are, since each has its mission as a refresher to the memories of the better informed.

But there is another class of periodical revelations which is less to be tolerated; which can only be safely launched upon the profession when there is some one at hand to detect the error and refute it as publicly as it was announced. While we would be patient with the hasty experimenter who doubtless has intended well, we cannot be too earnest in our condemnation of the fault which insufficient reading or observation has led him to commit. The young, the unwary, and the over-busy of our ranks are likely to be led astray, to their own serious detriment, and at the cost of the happiness of some with whose care they may be intrusted.

The particular class of startling and valuable "discoveries" to which attention is just now invited is that of tests for albumen and blood extractives as those substances appear in the urine.

Since the early days of the year 1869 our mental

vision has been blinded, and our confidence in old methods disturbed, by the sudden coruscation of at least four such meteoric announcements from abroad, and another which has been repeated at second-hand in our midst.

These are found: I. In an article by Dr. Owen Rees, F.R.S., on the Early Indications of Nephritic Irritation.

II. In the paper by Dr. C. Méhu, on a Process Employed in Testing for Albumen, March, 1869.

III. In Remarks upon Prof. A. Flint's paper upon Prognosis in Bright's Diseases, May 3d, 1869.

IV. In the announcement of Dr. C. M. Tidy, M.B., that he had found a far more delicate test than any other method that has been proposed.

V. In a second article by the same author, on a New Test for Albumen, *Lancet*, May 14th, 1870.

In a paper which appeared in Guy's Hospital Reports, 1869, Dr. Owen Rees reminds us that many years ago he called attention to the fact that in Albuminuria, extractives of blood always accompanied albumen, and that at times they appear before the albumen or after its disappearance, or, indeed, without its manifestation in any stage of the case. These extractives, he states, are to be detected by the tincture of galls, the reaction depending upon the precipitation of the impure lactate of soda, of Berzelius.

In cases of ordinary albuminuria it very constantly happens that the extractives continue to escape in considerable quantity when the albumen is about to disappear; so that, far from all being well, a constant and important drain is going on from the blood. This serves to warn us against too early a belief in convalescence.

But, says the Doctor, the habit of testing for extractives as well as for albumen becomes far more valuable in the detection of approaching albuminuria. We are cautioned, however, that we are only entitled to regard the escape of blood material as proving the existence of congestion or inflammation of some portion of the urinary surfaces. General symptoms must indicate the position and character of the lesion.

Sometimes we determine the presence of extractives although albumen is absent, and thus show that the kidney is really suffering from irritation, and we shall rarely be wrong in suspecting calculus, even though general symptoms abate, if we get a persistent reaction with galls. We may predict that albumen, blood, or pus will probably appear, sooner or later.

In cases of Addison's and Hodgkin's diseases, the urine should be examined. In a case of the latter (deposit in the spleen, with enlargement of the lymphatic glands) the urine was found highly charged with blood extractives, though free from albumen. Some days afterward a slight trace of albumen appeared.

We are further reminded that the reaction above noted is that observed to follow immediately on addition of the tincture of galls. Earthy and potash salts are thrown down from all kinds of urine by the alcohol in the tincture, after the lapse of five or ten minutes. Dr. Rees therefore proposes a fluid containing proof spirit and gallic acid, forming a very dark reddish-brown tincture, as a urinary test. If it is capable of accomplishing all that he thinks it is the profession is certainly deeply indebted to him.

Upon trial of this tincture with specimens of morbid urine in which an escape of blood extractives, or at least of minute proportions of albumen, seemed probable, although the usual tests carefully applied failed to detect it, we obtained the following results: In every case the tincture, in the first place, gave the urine a very dark color, and, in the second place, produced immediately a faint degree of turbidity. Here were two conditions calculated to interfere with one another, and render the decision as to the results of the test difficult. This was particularly the case, since the cloudiness, or precipitate, showed no tendency, after standing, to subside and form an appreciable sediment.

If the result were to depend alone upon color-change in a clear fluid, or upon turbidity produced in a previously transparent medium, only a minimum of difficulty would oppose the observer. But the turbidity, itself due to a whitish precipitate, and varying in different cases in amount, necessitates a change of shade in the color of the combined tincture and urine. The color of the urine, moreover, being subject to considerable variation, further complicates the application of this test. Its use by mixture and agitation with the urine proved unsatisfactory, and was abandoned.

Experience has shown that alcohol will cause a precipitate in perfectly normal urine. Dr. Harley * considers the substance thus separated to be allied to peptone. The same material is thrown down by chloroform, as Gigon was the first to show. But Harley considers absolute alcohol superior as a test to chloroform.

These facts, and the further knowledge that tincture of galls was formerly much used as a test, suggested the propriety of searching for the reaction pointed out by Dr. Rees in a series of specimens of normal as well as of abnormal urine.

The number of cases in which the test was applied was thirty-two, not selected, but such as occurred in the routine of business, the majority of specimens having been sent by other practitioners for examination.

Of these cases, twenty-four were males, eight were females, and one is unknown.

Five were in perfectly good health.

Three had more or less debility, without other disease.

Two had oxaluria.

Seven had relapsing fever.

Three had diabetes mellitus.

Two had renal congestion, one of these cystitis also.

Two had evident Bright's disease, one of these the waxy form.

One had hæmaturia and epilepsy.

One had syphilis.

One had alcoholismus, with albuminuria.

One had typhoid fever.

Four suffered from diseases unknown to me.

Albumen could be detected in 10 cases, in proportions varying from a trace to more than $\frac{1}{3}$ the bulk of the portion tested. In the remaining 22 cases heat and nitric acid failed to give any evidence of the presence of albumen. In every one of these cases the tincture of galls gave a cloudy precipitate, in the normal as well as in the morbid specimens.

In each instance undiluted commercial alcohol was added to a second portion of urine, with a view to ascertaining the effect of this reagent upon human urine, and also to see whether the alcohol of the tincture might not serve to explain, in part at least, the reaction obtained with galls. Both reagents were gently poured upon the urine, in an inclined test tube, with a slight, but only a slight admixture. In every case, at the point of contact a narrow whitish cloud appeared, generally wider and more evident when the admixture had been more thorough or extended. In all but two cases the alcohol produced a decidedly more distinct cloud ring or band than the tincture. These were cases of relapsing fever, one of them having $\frac{1}{7}$ albumen in his urine, the other having none.

In the albuminous case the tincture gave a copious

* Harley on Albuminuria. London, 1866, p. 9.

cloud, the alcohol one less marked. In the non-albuminous case the cloud with alcohol was very slight, but quite distinct with the galls.

What now are the conclusions which we deduce from the foregoing statements? Plainly these: 1st, that alcohol will produce a white cloudy precipitate of urinary extractives in all, or nearly all specimens of human urine; 2d, that tincture of galls, both on account of its spirituous and its acid constituents, will behave in a similar manner; 3d, that Dr. Rees was premature in supposing that the reaction which he obtained was possessed of the importance which he attached to it.

To this conclusion Dr. Beale* bears tardy support. In reference to the matter he says: "Healthy urine is scarcely affected by tincture of galls, but this blood-extractive is at once precipitated by it." The "scarcely" grants our point. Healthy urine *is* affected by tincture of galls; and we add that it is affected in the same manner as when the hypothetical "blood-extractives," which we believe to be simply urine-extractives, are present. If there is any difference, it is simply one of degree. The test, then, is valueless. We cannot undertake to form prognoses of a serious nature on such bases. Confessedly the object of searching for or announcing such a test is that of supplying a means more delicate or far-reaching than that which we possess already for the detection of disease. The failure is evident if persons in robust health, and as in our cases not taken sick in any manner after the lapse of at least four months, supply the same reaction as those seriously, nay fatally, ill.

The II., IV., and V. new tests are allied in character, and may be treated of in succession. They have one element in common—carbolic acid. The fashion which prevails in regard to the use of this substance has even caused it to become a urinary test; and a test for albumen. The fact that creasote has the property of coagulating this material is mentioned by Thudichum† and Roberts.‡ The latter moreover states that creasote and carbolic acid are unsuitable for urine testing, because they precipitate also some of the natural constituents of that excretion. If we accept the conclusion of Gigon§ and Harley‖ that peptone, or albuminose, exists in normal urine in small proportion, the evidence against the propriety of applying this reagent in the manner suggested is still stronger, showing, in fact, that we might expect a precipitate in every case in which the test was used.

Robin and Verdeil¶ affirm that not only creasote, but alcohol and tannin precipitate this modified albumen. Nisseron** confirms this statement in relation to creasote and alcohol.

The first of these carbolic acid tests for albumen is that proposed by Dr. C. Méhu, in an article of considerable length in the *Archives Générales de Médecine*, March, 1869. The author treats of the various tests for albumen which have been in use hitherto, and adds an account of the composition and modes of application of this which he calls the "Phenic Acid" reagent.

He writes: "The power possessed by phenic acid, creasote, and many other substances to coagulate albumen has long been known. The study of this property has led us to a process of direct treatment of albumen which we have practised for about 18 months at Necker Hospital.

"Dissolved in three or four times its volume of alcohol, phenic acid coagulates albumen readily; but such a solution precipitates at the same time the greater part of the mineral salts; it has, besides, other inconveniences which render its use impossible. By adding to the alcoholic solution of phenic acid a certain quantity of acetic acid, one need no longer fear the precipitation of salts.

"This is the formula of the reagent:

Phenic acid, crystallized, 1 part by weight.
Commercial acetic acid, 1 part.
Alcohol, at 90°, 2 parts.

"This solution may be kept an indefinite length of time without any alteration. Ten cubic centimetres thrown into non-albuminous urine, or into water, dissolve completely, and the liquid remains clear.

"In order to treat the albumen of urine, take 100 grammes of this liquid, add to them 2 cubic centimetres of commercial nitric acid, stir well with a glass rod, then add, by means of a pipette, ten cubic centimetres of the phenic solution.

"In fresh urine not albuminous, the reagent precipitates a little mucus; therefore it is necessary to work upon urine filtered after slight acidification by acetic acid."

Our experience indicates that the results obtained by this method are not so valuable as its author considers them.

We have already alluded to the facts that alcohol, and carbolic, phenylic, or phenic acid, are capable of producing a precipitate in all human urines.

With regard to the third ingredient, acetic acid, we remember that Reissner* showed that this acid, with heat, precipitates mucine in flocks. Experiment has proved to us that the action of the heat in this case is simply to hasten a process which will take place eventually in every specimen without heat.

Thus all of the ingredients of Méhu's test are capable of precipitating some one or more of the urinary constituents. We do not know how much the action of the acetic acid may be hastened by its combination with the other ingredients.

So much for the probabilities in the case. To ascertain the actual value of the reagent, it was applied in each of the thirty-two cases before mentioned, and indeed in several others not noted.

The test tubes were filled to one-third or one-half of their capacity with the urine. They were then much inclined, and the reagent slowly and gently poured upon the surface with as little admixture as possible. The tube was then brought to the perpendicular position. The more or less yellow urine was now seen to be very easily distinguished from the perfectly white and transparent reagent above. Gentle agitation secured a slight admixture of the two at the line of contact; and in every case an easily recognizable white cloud ring was seen to be produced within a few seconds. This precipitate was in some cases of normal urine decidedly faint; in other specimens of highly albuminous urine it was dense and almost solid.

The proposer claims that in unfiltered specimens this coagulation is due to the presence of mucus. In our experiments it appeared as well in carefully filtered specimens, whether acidified or not, as in those which were not so treated. We do not think that the cloud is one of mucus, but of urinary extractives; albuminose, most probably.

The application as explained by Dr. Méhu is so trou-

* Nisseron, op. cit., p. 176.

blesome as to forbid the general use of his test, even if it were otherwise desirable.

Much of this detail we found not only unnecessary, but even less capable of giving the best results than a simpler procedure.

The filtering we omitted in clear and acid urines. The measuring of proportions was found useless; and lastly, the addition of nitric acid to acid and to albuminous specimens was found to interfere with the clearest appreciation of the power of the test.

The IV. and V. of the new tests were proposed by Chas. Meymott Tidy, M.B, joint lecturer on chemistry at the London Hospital.

Both are spoken of as exceedingly sensitive in the detection of albumen.

We are prepared, after careful experiment, to grant that the reagents are both of them very sensitive; but also further to insist that they are useless as applied to the urine, since they throw down precipitates in normal as well as in albuminous specimens.

They are both of them carbolic acid tests, as before stated. The first is formed by a mixture of phenylic with acetic acid. The second by alcohol and carbolic acid.

The first test is prepared and applied as follows: Equal volumes of the two acids are mixed. A little water is then added in a test-tube, to ascertain whether the liquid, after being well shaken, becomes perfectly clear. As a rule, this proportion is about correct; but if the fluid does not become clear, a little more acetic acid is added, and it is tested after each addition, until the desired point is reached.

With a view to testing the value of this suggestion, we resorted to experiment. Four specimens of normal urine were obtained from as many persons in good health. They were carefully filtered through double thicknesses of fine filtering-paper. To sixteen fluid ounces of one of these was added one drop of albumen from a fresh hen's egg. The pipette with which this was done gives 95 drops of this albumen to the fluid drachm, as the average of these experiments. The proportion of albumen, as it is found in the egg, to the urine, in volume, was therefore less than 1 to 12,000.

The urine had an acid reaction, a deep amber color, a specific gravity of 1030, was transparent, and threw down a slight sediment of mucus. It gave no reaction with heat before being treated with albumen, and none others with strong nitric acid than the usual change of color and some effervescence in strongly heated parts of the tube. All four specimens had similar properties, and were similarly treated.

Portions of the urine without albumen, and with the same, were then subjected to Dr. Tidy's tests. The reasons why we resorted to urine rather than to pure water for these purposes were twofold: In the first place, so small a proportion of albumen is insoluble in such an excess of pure water; the salts being dissolved by the water, the albumen appears as one or more flakes, in proportion to the activity with which it is stirred. In the second place, it was desirable to ascertain whether the tests did or did not react with any of the normal urinary constituents. The results were the following:

The mixture of the two acids is heavier than urine, and the latter was consequently poured upon the former. The reagent behaved in the same manner with albuminous and non-albuminous specimens. At the point of contact a white cloudiness appeared of but slight density, but evident. The same effect was more generally produced by thorough admixture of the whole.

In endeavoring to follow accurately this method, it was found impossible to make the mixture of acids perfectly colorless and transparent after the addition of water, which caused them to become milky-white through precipitation of carbolic acid in minute globules.

The test is valueless, therefore, for the same appearances are given in albuminous and non-albuminous urines.

Tidy's second and newest plan is this: "Add to the liquid to be examined, in a test-tube, ten minims of alcohol (I employ it with a specific gravity of 0.805), shake thoroughly but gently, so as to avoid the production of froth. Then drop in the same quantity of carbolic acid and shake very thoroughly. Allow it to stand for a minute; and if the merest trace of albumen is present, distinct flocculi will be seen floating in the liquid. The alcohol and carbolic acid may be kept mixed, although I think it is more delicate when the experiment is made by dropping them in separately."

This test was used with the specimens, above referred to, of slightly albuminous and non-albuminous urine.

The alcohol mixed with portions in a test-tube without apparent change. But upon adding the carbolic acid and agitating freely, very active frothing occurred, and the fluid was left slightly cloudy. This was observed in all specimens. After standing some time, the flocculi mentioned by our author were distinctly to be seen in both albuminous and non-albuminous specimens. These were examined microscopically, and presented similar appearances. They were thin, slightly granular or perfectly hyaline, much corrugated membranous flakes. In one of the non-albuminous specimens undissolved globules of carbolic acid were found adhering to some of these coagula.

We may conclude, therefore, that carbolic acid tests, though very delicate detectors of albumen, are not applicable to the urine, since they precipitate certain constituents normally present in that fluid.

Now all this effort, which we have related, to discover very delicate tests for a very important morbid constituent of urine, naturally excited the inquiry, What is the delicacy of the tests commonly employed?

A few experiments were made to ascertain the proper reply to this question.

A portion of the normal urine containing one-twelve-thousandth of albumen as found in the egg was placed in a clean test-tube, reaching perhaps 3½ to 4 inches from the bottom. The flame of an alcohol lamp was then applied to the *upper portion* of the urine, leaving the lower cold.

After free ebullition had been produced, a clean wet rag was used to remove all traces of carbon from the exterior of the glass. This was done with as little disturbance of the fluid as possible. The tube was then held to the right or the left of the main avenue of light, inclined as much as possible, with the bottom away from the observer, so as to cause a foreshortening of the column of fluid, and hence a heightening of the effect of any change which might appear in either the cold or heated strata, since the transmitted light must come through a longer column of fluid to the eye. In addition to these precautions, it is well to hold the tube before a white surface placed in the shade, having a black patch of paper or paint upon it, which will assist the eye by the contrast, which can be constantly renewed if one but move the tube back and forth from the black to the white surfaces.

While the tube is between the white surface and the eye, the impression made upon the retina by light transmitted through the urine from the black surface is

lost; but this aids in keeping the eye sensitive to delicate variations. We are in the habit of keeping up this to-and-fro movement until certain as to the result in any given case.

Heat thus applied produced a distinct though very delicate cloud of albumen, not removed by dilute nitric acid, but rather increased. The strong acid produced so much color change and effervescence as to obscure the results.

Here, then, is food for reflection! The usual secretion of urine may be computed at from 30 to 60 fluid ounces per diem. If a person loses as much albumen from his blood by way of his kidneys as would be equivalent to from one and one-half minims to three minims of the uncoagulated white of a hen's egg, heat, with proper precautions, will detect the same!

The sensitiveness of the test, in other words, is such, that 1 part in more than 12,000 may be coagulated. Adopting the most careful methods, we were unable to detect albumen by nitric acid, either dilute or pure, until the proportion had been increased to 1 part in 6,000. When urine albuminous to this extent was gently poured upon the strong acid, a faint whitish cloud was seen at or just above the line of contact between the two fluids.

Thus we may conclude that heat is a more sensitive test than nitric acid, and as much so as we really need to have it.

If we are dealing with alkaline urines, we must render them acid; if we have turbid specimens, we must filter and refilter them with double or triple thicknesses of the finest paper, until the salts or vibriones are removed. In fine, we must go out of our way to obtain perfectly fresh specimens for examination.

In conclusion, we must refer to the III. new test which has been proposed to us for the recognition of albumen. It is the cupric-oxide test.

In the discussion following a paper read before the County Med. Society, the following remarks were made:

"A test for albumen, more delicate than those commonly employed, was identical with Trommer's test for sugar. Some specimens of albuminous urine would yield no precipitate with heat or nitric acid; but on treating them with a solution of sulphate of copper and potassa, the supernatant liquid, after the subsidence of the precipitate, would be left of a beautiful and characteristic purple color. The presence of grape (diabetic) sugar did not interfere with this test; so that both sugar and albumen might be tested for at once, the sugar being shown by the cuprous oxide, and the albumen by the purple color."

This test also was applied to the highly dilute solutions of albumen already mentioned. The reaction did not occur with specimens in which nitric acid sufficed to produce a coagulum. In considerably stronger solutions, however, the mauve was finely brought out.

Our most delicate and trustworthy test for albumen as found in the urine, then, is heat.

Next in sensitiveness and equal in importance is nitric acid.

In testing for very slight traces of albumen with heat, it is desirable to use dilute nitric acid.

The cupric-oxide test is at times convenient, but less trustworthy and delicate than the foregoing.

The tannic or gallic acid tests, and those containing carbolic acid and alcohol, are not to be used, since they produce precipitates equally in normal and abnormal specimens.

In fine, we have found ourselves to be already possessed of tests for albumen in every sense better than the new ones which have recently been suggested.

Vaccination in India in 1818.—In an old report on *Vaccination*, made in 1818, by Rev. J. A. Dubois, of India, we extract the following: "I have vaccinated, since my arrival in this country, nearly a lac, or one hundred thousand persons. Not one case has proved fatal, nor a single well authenticated instance, among this large number, of the small-pox recurring after the regular vaccine." He also asserted that the vaccine frequently put a stop to the intermittent fever which prevailed in that country. He knew instances of its curing quartan fever which had continued four or five years.

Thomas Jefferson's Idea of Medical Teaching.—In 1818 Thomas Jefferson, President of the Board of Commissioners for the University of Virginia, in laying out a plan of medical instruction for the University, thus discoursed: "Medicine, where fully taught, is usually subdivided into several professorships; but this cannot well be without the accessory of a hospital, where the student can have the benefit of attending clinical lectures, and of assisting at operations of surgery. With this accessory the seat of our University is not yet prepared. For the present, therefore, we propose but a single professor for both medicine and anatomy."

The Stethoscope First Introduced.—Dr. Laennec physician to the Necker Hospital, Paris, first introduced this useful instrument in the year 1818.

Cheating the Doctor not a new Idea.—In 1715 Sir William Smyth, of Bedfordshire, a relative of Dr. William King, St. Mary Hall, Oxford, when he was near seventy, was wholly deprived of his sight; he was persuaded to be couched by Taylor, the oculist, who, by agreement, was to have sixty guineas if he restored his patient to any degree of sight. Taylor succeeded in his operation, and Sir William was able to read and write without the use of spectacles during the rest of his life; but as soon as the operation was performed, and Sir William perceived the good effects of it, instead of being overjoyed, as any other person would have been, he began to lament the loss (as he called it) of his sixty guineas. His contrivance, therefore, now was, how to cheat the oculist; he pretended that he had only a glimmering, and could see nothing perfectly; for that reason the bandage on his eye was continued a month longer than the usual time; by this means he obliged Taylor to compound the bargain and accept of twenty guineas. Sir William was an old bachelor, and at the time Taylor couched him, had an estate of land valued at one hundred thousand pounds, besides a large sum of money in stocks, and not less than five thousand pounds in his house.—*British Critic.*

Infants Sacrificed in China.—Rev. Mr. Abeel informs us that in the Fuh-kien Province, China, forty per cent. of the female infants are sacrificed by their mothers.

Various Names for Epidemic Cerebro-Spinal Meningitis.—Dr. J. Netten Radcliffe (*Med. News and Library*) publishes the subjoined technical synonyms for this fever: Cerebro-spinal fever (*Royal College of Physicans*); cerebro-spinal arachnitis; typhus syncopalis; tifo apoplettico tetanico; typhus cerebro-spinal (*Boudin*); cerebral typhus; epidemic meningitis (*Stillé, U. S.*); petechial fever (*G. B. Wood, U. S.*); fever with cerebro-spinal meningitis (*S. Gordon*); malignant purpuric fever (*W. Stokes*); malignant purple fever; nervo-purpuric fever (*Mapother*); malignant purpuræ (*M'Swinney*); pestilential purpuræ (*Banks*); febris nigra (*R. D. Lyons*). *Popular names:* Spotted fever (*New England*); cold plague (*Southern States, U. S.*); Kolik, Hackenstarre, Genickkrampf (*Germany*); Nacksjuka, Dragsjuak(*Sweden*).

AMPUTATION AT THE SHOULDER.—W. F. McNutt M. D. (*Cal. Med. Gazette*), thus describes his method of amputation at the shoulder-joint:—On the night of Nov. 23d, 1863, he went on board the steamer "Black Hawk," and found a man whose left arm was so severely injured by a six-pound shell that amputation was necessary. Having no one with him that he could persuade to attempt the compression of the artery, or even to have anything to do in any way with the chloroform, the shoulder was amputated as follows: Chloroforming the patient thoroughly, the knife was passed close by the acromion, gliding it over the humerus to appear at the posterior fold of the axilla, and cutting outwards and downwards, the posterior or external flap was completed. An assistant holding the flap up, he opened the joint, forced the head of the bone outward, and pressed the knife behind it and close to the shaft of the bone. Paymaster Whitehouse then taking the arm, Dr. McN. placed his left hand in the axilla, and, with the palm to the flap, the thumb passing along the back of the knife, he had a firm grasp of what was to be the anterior or internal flap, which of course contained the vessels; then cutting on, he finished the internal flap. Taking up the forceps the arteries were seized and tied. There was scarcely any hemorrhage. As he had no one to keep the patient under chloroform rapidity was a great desideratum. Under the same embarrassing circumstances, he would feel inclined to operate in the same manner, rather than that of Verneil's method, which is now in vogue in France.

THE ORIGIN OF MANNA.—Mr. Daniel Hanbury, F.R.S., at a recent meeting of the Pharmaceutical Society, alluded to the early history of manna, and stated that modern manna is derived from a species of ash cultivated in Calabria and in Sicily. The following points were brought out in the discussion: 1st. That the manna known in Europe in very early times was probably of Oriental origin. 2d. That the manna of the ash began to be collected in Calabria in the first half of the 15th century. 3d. The practice of making incisions in the trees in order to promote the exudation was not commenced until about the middle of the 16th century, previous to which period the only manna obtained was that which exuded spontaneously. 4th. That although the existence in Sicily of a mountain called by the Arabian name, *Gibilmanna*, would seem to indicate that manna was collected during the period of Mussulman rule in the island, evidence has not been produced to prove the fact, but that, on the contrary, it appears that manna was gathered in Calabria long anterior to its collection in Sicily.—*Chemist and Druggist.*

A CASE OF DIAPHRAGMATIC HERNIA.—Dr. Borland, of Boston, Mass. (*The Boston Med. & Surgical Journal*), reported at a late meeting of the *Boston Society for Medical Improvement*, a case of diaphragmatic hernia, and showed the specimen, taken from a man 31 years old. In this case the hernial opening was in the left side of the diaphragm.

Dr. Bowditch says as to the diagnosis, that there were only two recorded instances of the recognition of diaphragmatic hernia—one by Mr. Lawrence, of London, and one case at the Massachusetts General Hospital.

A PATENT MEDICINE MAN TURNS UNDERTAKER.—There is a tide in the affairs of men which, taken at its flood, leads on to fortune. A Massachusetts man, who has for months sold a patent medicine, has just in the nick of time turned undertaker.

SUDDEN DYSPNŒA RELIEVED BY VENESECTION.—Dr. Cheever, of Boston, Mass. (*Boston Med. and Surg. Journal*), was called in haste, in the evening, and found a lady, æt. 35, who, twenty minutes before, was suddenly seized with intense dyspnœa. Ipecac. grs. 120, in successive doses, and mustard ʒ ij in hot water, produced no emesis, nor nausea. Brandy and ammonia were given to sustain the overloaded heart. No amendment followed, and she was apparently about to die, when Dr. C. removed one pint of blood from the arm, believing this procedure the only way to set up *endosmosis*, and turn the tide. The blood was black, and sluggish in running. The first 8oz. produced no effect. Then the pulse began to grow stronger, the breathing easier, and the color better. When the pint had been taken the patient lay down, breathed easily, and the color became florid. She recovered in a few days.

The case bears resemblance to one reported by Dr. Abbot a year ago; and to recent cases narrated by Drs. Cotting and Fifield.

OCULAR TUMORS.—H. Knapp, M.D., of New York, says: "Were I to rely on my own observations, ocular tumors would hardly admit of more than two varieties, viz. *glioma*, originating in the retina; and *sarcoma*, proceeding from the choroid, and being in part unpigmented and in part melanotic."

INDURATION OF THE SPINAL CORD.—J. Netten Radcliffe, M.D. (*Med. News and Library*), in his paper on "Diseases of the Spinal Cord" remarks: Like the opposite condition of softening, induration (sclerosis) of the spinal cord is one of the consequences of myelitis, chronic or acute; of the chronic form more especially. Induration of the cord is generally associated with atrophy—atrophy often more marked in the white matter than in the grey—and with a condition so curiously bloodless that a section is not unlike that of white of egg boiled hard. In its highest degree the cord may have a leather-like or fibro-cartilaginous hardness and consistency. Induration is a much less common change than softening; it has no symptoms by which it can be distinguished from softening; and it is often met with when it was not expected, and under very different circumstances, as after acute myelitis on the one hand, or after long-standing epileptic disease on the other.

PALATABLE FORMULA FOR THE HYDRATE OF CHLORAL.—Hydrate of chloral, ʒ ss., chloroform water, ʒ ij., syrup oranges or tolu, ʒ i-ij., tincture of ginger, 6 to 12 drops, water to one ounce and a half. The *chloroform water* is prepared by dissolving a half fluid ounce of chloroform in one gallon of water. This seems to intensify the action of the chloral hydrate and covers the acrid taste. —*The Rich. and Louisville Med. Journal.*

DOUBLE VAGINA.—J. C. Davis, M.D., Fort Atkinson, Jefferson County, Wis. (*The Chic. Medical Journal*), while examining the external organs of generation of a young lady, aged 21 years, discovered a septum commencing at the mesial line (in a line from right to left), attached to the meatus urinarius, and extending laterally and posteriorly two-thirds of the way to the fourchette, and within the vulva and hymen. The external genital organs were well developed. The mons veneris well covered with hair. The labia majora and minora were perfect. The os uteri was in the right vagina (or vagina proper), which was of normal size, shape, and capacity.

DEATH OF AN OLD LADY.—Mrs. Hannah Fennimore died at Delaware City, Del., August 12th, at the advanced age of one hundred and eight years.

PRESCRIPTION WRITING.

THERE is hardly anything that bothers a young practitioner more than the proper writing of a prescription. We are indeed convinced that this is so much the case that for the sake of making the recipe he will too often restrict himself to a very few formulæ with which he may be acquainted rather than run the gauntlet of incompatibilities in search of remedies that he is pretty sure would answer his purposes better. And after all he is not so much to blame as we might suppose, inasmuch as he has really had very few if any opportunities for becoming acquainted with this most important of arts. His teacher of materia medica is generally too intent upon the physical properties of the drug, its habitat, mode of preparation for medicinal purposes, etc., to give much of his time to the discussion of its doses, incompatibles, or particular method of administration. A lecture or two is delivered upon prescription writing, in which perhaps the different signs for weight and measurements are given, and the reasons for rendering the ingredient in the genitive case and the quantity in the accusative. Then perhaps a few of the hackneyed Latin directions are translated, and this in most instances completes the plan upon which the beginner is to build his practical knowledge of therapeutics. While most practitioners, thankful even for this start, are willing to master the art, the great majority find it much more convenient to keep in the narrow rut of routine. This would be well enough if such a performance of responsible duties were all that were required of the physician, but unluckily this is not so. John Radcliffe nearly two hundred years ago uttered a truism which holds its own to a certain extent, at least at the present time:—"When I was a young practitioner I knew of twenty remedies for every disease; now (near the conclusion of his life) I know of twenty diseases for which there is not a single remedy." The young medical man is always confident of his few remedies which may be lauded by his medical teacher, and theoretically he cannot see how they should fail in producing remarkable cures. How often, however, is he surprised to find, when actually tested, that they are utterly useless, and this too when the diagnosis of the disease is perfectly correct. It will be oftentimes fortunate indeed for his confidence in the particular and favorite remedy if it can be proven satisfactorily to his own mind that the said drug or salt was impure. When one article fails he is expected to stand ready with another and another, and have a knowledge of its necessary combinations literally on his fingers' ends.

The successful prescriber is the successful practitioner, and the necessities of his situation and surrounding circumstances compel him to be constantly on the look-out for new remedies and new methods for administering them. The opportunities for learning of the new articles are very abundant, but beyond these the practitioner is mostly left to his own ingenuity and resources. No pains seem to be taken by such as may become practically acquainted with the most agreeable vehicles of administration or the most effective combinations to make such information the property of the profession at large. It seems to be generally sufficient for their purposes to state that in such and such an interesting case such and such an article was given with such a result, the particular dose not even being mentioned. If a writer thinks this a matter of minor importance he mistakes very much the necessities of the general class of practitioners. We do not hold it to be generally necessary to state day by day when the patient urinated, when the bowels moved, when he slept, when he turned over, gaped, or snored, but it is certainly in keeping with the requirements of good therapeutics to mention not only the articles used, but the doses and the manner in which they were employed. A good prescription is as much a part of the history of a case as any record of the temperature, pulse-wave, or the respiratory murmurs, and as such should have its due prominence. It was on account of this oversight by many medical writers that for a long time many excellent medicaments were unemployed by the profession, and many manœuvres in their administration were unknown, and consequently unused. Take as an instance hypodermic injections. We can look back to the time when, despite the testimony of a few in their favor, they were seldom attempted for the want of the necessary explicit directions as to the kind of instrument required, its proper use, and the necessary strength of the injection. Again: here is our new remedy, chloral—how few at present have succeeded in accordance with their expectations in its administration, and how many have on account of this really unblamable ignorance been forced to give it up entirely!

The relative doses in which some medicaments are given when in certain combinations are oftentimes so variable, and, as regards effects, so important, that the best plan would seem to be to give the prescription in full. Such a practice by our writers and teachers would not only advance the science of therapeutics by

rendering more exact our knowledge of remedies, but would constantly familiarize the tyro with the most approved method of writing a prescription. What an immense amount of good, in these respects, would it do to the student of medicine if his clinical teacher, when prescribing for patients, would write out in full upon a blackboard the formula used in each case!

So much attention is given to prescription writing abroad, especially in Great Britain, that it forms a regular part of the medical education of a student, and the examination into his practical qualifications as a prescriber is as rigid as on any other branch. We should be afraid to state how few of our candidates for graduation could pass such an examination. Again:—much more attention is given to methods of prescribing abroad than with us. Medical authors, of Great Britain especially, are in the commendable habit of publishing their favorite recipes as an appendix to their works, a practice almost entirely ignored here. In fact, we can point to but two or three works on general medicine, by American authors, in which such a plan is adopted at all.

We hope to see some reaction in this particular, that it may not be said that prescription writing has become with us a lost art.

Among the curious things to notice regarding Army Medical service in the Franco-Prussian campaign is the protest on the part of the French Minister against the employment of American Surgeons by the Prussian army. If one country sees fit to bring to the aid of its wounded the best skill it can obtain, it shows an enlightenment so much above censure that a failure to do likewise on the part of the protesting party gives rise to uncomplimentary reflections. Surgeons have always been considered non-combatants, and there is wanting proof to show that they have not always been true to the cause they have espoused, and have not been alike ready to help friend or foe.

Reviews and Notices of Books.

The Practice of Medicine. By Thomas Hawkes Tanner, M.D., F.L.S., Member Royal College of Physicians, etc. Fifth American, from sixth London Edition. Enlarged and thoroughly revised. Philadelphia: Lindsay & Blakiston. 1870. 8vo, pp. 1200, cloth.

Dr. Tanner's Practice of Medicine has some features which are peculiar as compared with others now before the public. Grown as it has from a handbook to a volume of twelve hundred pages, it has lost nothing of the terseness of the former, added to which are descriptions of many diseases and their treatment not usually found even in a volume of this size. As an encyclopædia of the practice of medicine it serves its purpose well. But what we gain in variety we occasionally lose in fulness of delineation and thoroughness of detail. This truth is manifest in the description of some of the more common and interesting diseases which the practitioner is called on to treat. As a work of reference for the physician in an emergency, or for one who has not much time for reading, it will answer the aim of its talented and studious author. As a complete treatise, however, it is not so well adapted to the American practitioner as many others by our own medical writers. This is particularly the case with many of the formulæ in the Appendix, prepared as they are according to the British pharmacopœia. His remarks on the mineral springs and climates for invalids, while they are necessarily of immense value to our transatlantic confrères, are not of much account to us here, surrounded as we are by springs of almost every character and with a diversity of climate which is likely to suit the requirements of almost all invalids. We cannot help concluding that the American edition could have been much enriched by a judicious medical editor who could adapt it to the real wants of the American physician. It is supplied with a copious index, and is well printed and handsomely got up.

As Regards Protoplasm, in relation to Professor Huxley's Essay on the Physical Basis of Life. By James H. Sterling, F.R.C.S. and LL.D. Charles C. Chatfield & Co., New Haven, Conn., 1870.

This is the third number of the University series, and contains by far the best and ablest reply that has yet been made to Huxley's well-known essay on protoplasm. All who have read the latter should by all means make themselves familiar with Sterling's arguments on the opposite side.

Correspondence.

THE THERAPEUTIC USES AND ABUSES OF QUININE AND ITS SALTS.

A LETTER FROM

PROF. ROBERTS BARTHOLOW.

To the Editor of the Medical Record.

Sir—In your journal of August 1 (p. 262), Dr. Stephen Rogers appears in a letter on "The Hypodermic Use of Quinine," in which he refers to some opinions of mine as published in the Russell prize essay. Also, in *Vol. 20 of The Transactions of the American Medical Association*, I find an elaborate paper by Dr. Rogers "On the Prophylactic and the Therapeutic Uses and Abuses of Quinine and its Salts," in which he is at much pains to set forth and to animadvert on my views on the subject. I am bound to say that his frequent references to me are often offensive in tone, and are, apparently, intended not so much to vindicate the truth as to air some private grievance. Indeed, in his paper in the Transactions of the American Medical Association (p. 187), he alludes to a "provocation to which this edition [of his paper] is indebted for its preparation." I beg to say that Dr. Rogers has had no "provocation" from me, yet his persistent attacks will incline the medical profession to think that I have been so unfortunate as to give him ground of offence. I can, however, affirm that I have alluded to Dr. Rogers' writings but in one instance, and then in decidedly complimentary expressions. Under these circumstances, it seems only proper that Dr. Rogers should state the nature of the "provocation" to which he has been subjected, and not deal in vague allusions which cause innocent parties to be suspected of some enormity, and confuse rather than enlighten the public.

But to pass from this merely personal matter to the scientific side of the controversy:

In his haste to "disagree in toto" with Dr. Bartholow, Dr. Rogers is betrayed into some inconsistencies.

Thus (Volume 20, Trans., p. 192) he remarks as follows:

"If the salts of quinia are antidotes to miasmatic poison, and *I do not doubt that they are*," etc. (Italics mine.)

Notwithstanding this positive statement in his text, I find him saying in a foot-note (p. 211 Trans. *supra*):

"From the views heretofore expressed as to the therapeutic *modus operandi* of quinia upon miasmatic disease, the reader will be prepared to hear that I totally disagree with Dr. Bartholow in the declaration that 'it can neutralize or destroy very perfectly the morbific matter.'"

A significant instance of the difference struck, in some minds, between *tweedle-dum* and *tweedle-dee*.

In the same foot-note just above quoted Dr. Rogers utters some extraordinary opinions which indicate that his knowledge of malarial diseases is entirely clinical, that he has not pursued any *post-mortem* researches, and that he has not taken the trouble to inform himself in the present state of scientific opinion in regard to the changes induced by malaria in the organism. Let me quote his own language to prove these charges which I bring specifically against him:—

"It is quite gratuitous to suppose, as does Dr. Bartholow, that because paroxysms 'recur from time to time' it is on account of structural changes in the organs of the body, especially of the liver and spleen. This, in my opinion, is pure speculation, totally undemonstrable, and not in any sense 'a fundamental fact' as he declares." (Foot-note, p. 211 Trans.)

I respectfully suggest to Dr. Rogers that he read without delay Trousseau's description (*Clinique Médicale de L'Hotel Dieu*, vol. iii., p. 418) of the *diathèse palustre*, and he will ascertain how far my statements are "pure speculation." In a foot-note in another place, he refers disapprovingly to my distinction between simple engorgement of the spleen, which occurs in every ague paroxysm, and that "fleshy condition" of the organ developed in the course of chronic malarial poisoning. If he will take the trouble to refer to Niemeyer (Am. Edition, vol. i., p. 712) he will find in a few sentences an admirable description of the "fleshy spleen." For proof that, in recent cases of malarial fever, the spleen is engorged, let him examine any text-book on practice. So far, then, from my views on the relation of the structural alterations to the objective phenomena of fever in malarial disease being "pure speculation," they are supported by the highest authorities. That my opinions cannot receive the approval of Dr. Rogers is evident not only in the foregoing, but in many subsequent statements. Even when our opinions are the same, he sometimes discerns a difference, as, for example, in a foot-note on page 205 of the Transactions. In this he refers to the "mathematical and summary way" in which "Dr. Bartholow disposes of this matter of the time and quantity of quinia," and yet, in his letter to the RECORD, he assigns, in a way quite as mathematical and summary, about the same quantity of quinia for the treatment of an intermittent as I had indicated in my essay.

Dr. Rogers is much exercised on the subject of my views as to the proper period for the administration of quinia. I remark in my essay on this point as follows:—

"If time is an element of importance, no delay is necessary in order to give the remedy in the stage of apyrexia.

"To save the suffering and exhaustion of the febrile movement the attack should be anticipated, and, if possible, prevented.

"As the maximum effect of the quinine is attained in about five hours after being taken, it should be administered this period of time at least before the expected paroxysm.

"As the elimination of quinine takes place with considerable rapidity (see *post*), the maximum curative effect is obtained by the administration of the whole amount required in a single dose, rather than by a succession of small doses."—(*Medical Communications of the Conn. Med. Society for* 1868, p. 102.)

These observations Dr. Rogers criticises in a foot-note (p. 206, Trans.) as follows:—

"Both physiological experiment and properly conducted clinical observations definitely establish the fact, that no medicinal quantity of quinia will exert a controlling influence on the economy against paroxysms of miasmatic fever for a longer time than about twelve hours. Therefore, if ten or twenty grains of quinia are taken in the sweating stage of a quotidian ague to-day, the daily paroxysm will, as a rule, return to-morrow, the cases in which such return is not observed being quite the exception. This I have demonstrated in thousands of cases. I disagree, therefore, with Dr. Bartholow in toto upon this point." Yet Dr. Rogers has no doubt as respects the antidotal power of quinia! I will, however, quote against this enormous experience, a paragraph from the work of the ablest clinician in the United States—Prof. Austin Flint.

"With respect to the time of giving the antiperiodic remedy, my experience has led me to the conclusion at which Bretonneau, Graves, Briquet, Trousseau, Murchison, and others have arrived, viz., that it proves most effective when given as near as possible to the paroxysm which has passed. It is probable that, if it be given in the sweating stage, the chances of preventing the next paroxysm are greater than if the administration be delayed until after this stage. As regards dose, the most effective plan is to give the remedy so as to produce cinchonism as speedily as possible."

It appears, then, that Dr. Rogers not only "disagrees in toto" with Dr. Bartholow, but also with the most eminent authorities. He should review his experience with those "thousands of cases."

On page 218 (Trans.) Dr. Rogers alludes to the use of quinia in erysipelas, and again refers to me in a foot-note in the following terms:—

"Dr. Bartholow seems not to have been acquainted with this important power of quinia, at least he does not allude to it."

As Dr. Rogers has taken so much pains to depreciate my clinical and experimental investigations on the actions and uses of quinia, I must call his attention to the remarkable manner in which my conclusions have been confirmed by a different method of inquiry pursued in another part of the world. Let me quote my observations:—

"*Acute Inflammations.*—The authorities agree as to the impropriety of using quinine during the acute stage of the inflammatory process. There are two conditions, however, in which, according to my experience, it is often exceedingly useful: the stage of congestion, or the formative stage of an acute inflammation; and the stage of resolution. . . So, also, idiopathic pleuritis, pericarditis, and peritonitis, may be rendered much more manageable, if not entirely cut short, by a large dose of quinia, given in the very incipiency of these diseases; but it is necessary, in order to achieve so successful a result, that the stage of effusion or exudation be not reached." I indicate on the same page a number of diseases in which it may be thus used with advantage, but conclude that "quinine ceases to be useful when alterations of structure or exudations have taken place."

In his remarkable researches on quinia, Binz (*Grundzüge der Arzneimittellehre*, Berlin, 1869, p. 75) has shown that this antiphlogistic effect is due to the action of quinia on the white corpuscles, the amœbiform movements of which it checks. Martin, in his inaugural dissertation (*Das Chinin als Antiphlogisticum*), has confirmed Binz's researches and added to them important observations of his own, showing that quinia arrests the migration of the white corpuscles, and acts as an antiphlogistic by its influence upon those processes resulting in suppuration.

I pass from this topic to the subject of the hypodermic administration of quinia, on my views in regard to which Dr. Rogers animadverts with some severity. He takes as his text a fatal case of tetanus, which followed the hypodermic use of quinia. An isolated case like this proves nothing. Tetanus has followed in some subjects the most trivial injuries, as, for instance, the puncture of a sewing-needle. According to Dr. Rogers' system of logic we should argue—the puncture of a needle having caused tetanus, needles should no more be used. He applied the same method to that other occasional accident of the hypodermic injection of quinia, the formation of abscesses. One would suppose from Dr. Rogers' statements that accidents from the internal use of quinine were unknown.

But I have a more serious quarrel with Dr. Rogers about the manner in which he quotes from my essay, to convey incorrect impressions in regard to my opinions. He has done this in quoting a portion of my remarks on the physiological effects of quinine hypodermically administered. My statement was as follows:

"It is a remarkable fact, confirming the doctrine of a specific action of quinia which is irrespective of its physiological effects, that the cure of malarious disease by subcutaneous injection is not *necessarily* accompanied by any evidence that can be recognized of an impression upon the nervous centres. The cure *may* be accomplished without any disturbance of the vascular system, without any alteration of the normal thermal line, and without any disorder of the cerebral functions."

Now, Dr. Rogers quotes only the last sentence to place my views in antagonism to those of the Committee of the Medico-Chirurgical Society. My meaning evidently is this: so small is the quantity which may be required to cure an intermittent, when the agent is injected under the skin, that physiological effects are not necessarily produced; in other words, that a curative effect may be reached without any appreciable change in the pulse, respiration, and temperature. I do not stand alone in this opinion. Dr. Chasseaud, who has had the most extensive opportunities for observation in the hospital at Smyrna, comes to the same conclusion; but Dr. Rogers, who admits that he has had no experience with the method, comes to the opposite conclusion. I must beg leave to say, in this connection, that the utility and efficiency of the hypodermic method of using quinia are too well established to be set aside on the *dicta* of Dr. Rogers. I hence pass from this to the only remaining topic which I purpose now to discuss, viz., the introduction of quinia *per rectum*. I cannot fail to note here some extraordinary language used by Dr. Rogers on this topic. In a foot-note to his paper in the Transactions (p. 233) he expresses surprise "that the fact should have escaped the attention of a man of Dr. Bartholow's intelligence and habits of observation that the *rectum is not a digestive organ*" (Italics Dr. Rogers'), and in his letter he states that I have "ignored this fact." This is a perfectly gratuitous observation on the part of Dr. Rogers, and is in no sense an argument. In my essay I have stated that when quinine is required in continued fevers it is better given by the rectum in suppository or clyster, to avoid the irritant effects of the agent on the gastro-intestinal mucous membrane. This remark gives occasion for his statement that I have "ignored the fact that the *rectum is not a digestive organ!*" According to Dr. Rogers' view, quinia in solution in water is better absorbed, and "quinine suppositories and quinine clysters, made with either pure water or some emulsive fluid, requiring digestion and solution, are more or less slowly and partially appropriated." Another exhibition of the remarkable difference between *tweedle-dum* and *tweedle-dee!*

Dr. Rogers "disagrees" with me also in regard to the quantum of physiological effect produced by quinia when given by the stomach and rectum respectively. It is true that some authors think the rectum takes up quinia as rapidly as the stomach, but it is generally conceded that as an absorbing surface the rectal mucous membrane is greatly inferior to the stomach. Trousseau et Pidoux, whom Dr. Rogers quotes from Stillé, say that quinia given in *lavement* may perhaps be somewhat less in quantity than when prescribed in *potion*, and this because absorption takes place better and more rapidly in the large intestine than in the stomach (*Huitième Edition, par C. Paul.* Tome Second Paris, 1869, p. 506). But this observation is not in accordance with generally accepted views, and will not, I am persuaded, be confirmed by those who make the trial.

ROBERTS BARTHOLOW.
27 WEST 8TH ST., CINCINNATI, Ohio.

TREATMENT OF DELIRIUM TREMENS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR—It has been incontestably shown that alcohol, when introduced into the animal economy, produces effects analogous to those of a poison; that is, it "acts in a noxious manner on the vital properties or textures of organs." By its operation the tissues are corrugated, albumen is coagulated, and the solidifiability of fibrine is impaired. Mucous membranes suffer irritation from its presence, and a state of actual inflammation may supervene upon its protracted use. Alcohol absorbed into the blood interferes with its proper aëration by the abstraction of its oxygen, and the impure blood, thus unfitted to subserve the wants of nature, tends to the production of functional disturbances, or may react, through the medium of the medulla oblongata, upon the nerves of respiration, and occasion death from asphyxia, as is the case in narcotic poisoning by other narcotic substances. (Carpenter.) General disorder of the powers of assimilation and a condition of greatly disturbed innervation are prominent features in all habitual drunkards, and the same deranged nutrition giving rise to those phenomena has its culmination in delirium tremens. In this disease, whether occurring in the midst of a debauch or after the suspension of the accustomed stimulus, the train of symptoms is always virtually the same. Debility, constipation, gastric irritability, preternatural vigilance, and various hallucinations, are its well known characteristics, and their proper management, I am confident, rests entirely upon the fulfilment of two indications, namely, the procurement of sleep, and the establishment of nutrition. Much that is absurd and hurtful has been written about, and practised in the treatment of, delirium tremens, but happily the disease is now sufficiently well understood to admit of a rational adaptation of means to ends.

The use of digitalis, tartar emetic, and the further saturation of the system with alcohol, as recommended by some writers, are measures calculated to do vastly more injury than good. At the outset it is usually desirable to correct the digestive derangement. A cathartic containing some mercurial, or a grain of podophyllin associated with extract of hyoscyamus as a corrigent, administered at once, is productive generally of good results. After this, or simultaneously, the exhibition of some hypnotic is of paramount importance. The patient must sleep or die. Formerly opium was almost solely relied upon for this purpose, but opiates stand in the way of nutrition—they suspend digestion, and this constitutes a fatal objection to them. Happily, however, we have now a remedy that promises to do the good of opium without the evil, namely, the hydrate of chloral. In many cases this remedy acts like a charm, and quickly induces sleep. Half a drachm, dissolved in mint water or syrup of tolu, with the addition of tincture of cardamom, will procure a good sleep, in ordinary cases, for an adult; and although the medicine alone is by no means palatable, it can be made so by the above combination, and in general sits well on the stomach and leaves it in good order for digestion afterwards. It acts promptly, commonly within ten minutes, and if it does not procure sleep in half an hour, the dose repeated will seldom fail to do so. It is not an anæsthetic—the patient is sensible of pain under its influence, but inclined to sleep.

The use of bromide of potassium, so highly spoken of by many, has not been attended with satisfactory results in my hands, although tested as thoroughly and fairly as possible. The chloral hydrate leaves nothing to be desired, so far as my experience goes.

In the fulfilment of the second indication (the establishment of nutrition), the animal broths, free from grease, and seasoned strongly with capsicum to facilitate absorption, will be found to answer well. They alone, or in connection with eggs, milk, or beef-tea, will most likely be assimilated by stomach digestion. If not, recourse should be had at once to nutritious injections. Effervescing draughts internally and sinapisms to the epigastrium are useful in allaying nausea. Of course, perfect quiet and freedom from all exciting influences cannot be too strongly enjoined as aids in conducting the case to a favorable termination.

P. F. Harvey, Assist. Surgeon U. S. A.

Fort Jackson, La., Aug. 15, 1870.

LABIAL HÆMATOCELE:

A CASE REPORTED

By CHARLES McBURNEY, M.D.,

HOUSE SURGEON, BELLEVUE HOSPITAL.

[The following letter to Prof. Barker, reporting a case of labial hæmatocele occurring in his service, has been handed us in illustration of his lecture upon the subject, published in our last number.—Ed.]

Bellevue Hospital, May 9, 1870.

Dear Sir,—You asked me to report to you a case of labial hæmatocele which occurred during my lying-in service of last month. I take great pleasure in doing so, hoping that it illustrates some of the points you make in speaking of that complication. The case is this:

Ann B——, 29 years old, primipara; a strong and apparently well-developed woman. The first stage of labor began at 4 P.M., April 27th; was not finished till 4 P.M., April 29th—48 hours after. Vertex presentation; position, left occipito-anterior.

The head became thoroughly engaged in the superior strait, but after the first half hour of the second stage did not advance at all, though the pains continued pretty good. At the end of the seventh hour the head was in exactly the same position. The woman was becoming exhausted, the skin and vagina hot and dry, pulse much more rapid, and pains feeble. At that time, 11 P.M., I was just on the point of going to consult you, when the woman called to me that "her womb had come down." I had just previously examined her, finding nothing unusual. On examination now I found a tense, dark-colored swelling of the whole of the right labium, about half the size of my fist, and evidently increasing in size. I judged it to be an hæmatocele, and immediately put the woman under chloroform, and called the House Staff to the ward. We considered it a case of emergency, as the tumor was rapidly increasing in size, completely occluding the vagina. So I made an incision from the upper to the lower extremity of the labium, turning out a large clot of blood, and was surprised to find no more hæmorrhage. The clot was situated just beneath the true skin, in the connective tissue. The long forceps were then easily applied, and the child delivered. They could not have been applied had the tumor remained, without great danger of tearing it from its base.

The woman has had no bad symptoms and no more hæmorrhage. To-day, ten days after operation, both she and the child are doing perfectly well.

Charles McBurney.

Dr. Fordyce Barker.

New Instruments.

NEW GALVANIC APPARATUS.

By GEO. M. BEARD, M.D.

I desire to call the attention of the profession to a new combination of Smee's elements, which I have em-

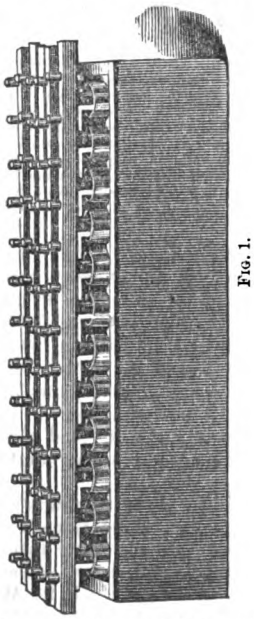

Fig. 1.

Fig. 1.—A much larger size of element is frequently used than the one here represented. Larger elements, which can be more easily cleaned and amalgamated, are frequently kept in the solution all the time without injury. It is not ordinarily desirable to have less than 40 large or 60 small elements. If the elements are too small, the current generated will be too weak, unless they are very frequently cleaned and kept in perfect order. This part of the apparatus may be taken out very conveniently, and carried, if it is first provided with some sort of a cover. It is not necessary to take out the box in which it is enclosed.

ployed for a number of months past, and which, in the various modifications of size, shape, and arrangement of which it is capable, will, I think, be acceptable to those who desire to use the galvanic current, either in hospital or private practice, in a stationary or portable form. The combination of 60 small elements, represented in Fig. 1, was made for me by Jerome Kidder, in 1869. I had before suggested and tried other combinations of Smee's elements, but had not met with the success I desired.

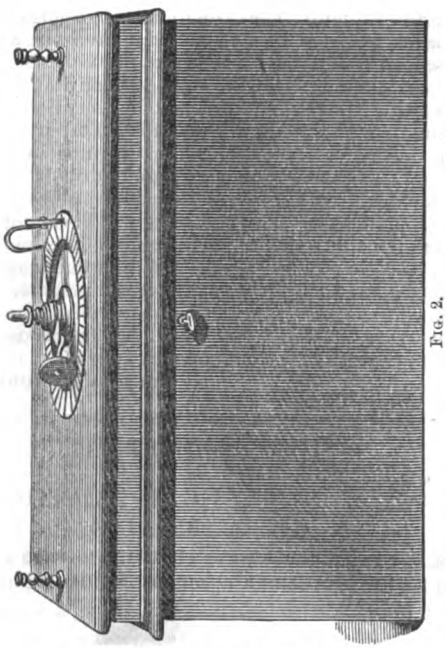

Fig. 2.

Fig. 2.—*Kidder's galvanic apparatus, with box and cover.* One of the wheels in the middle of the cover connects any desired number of cells from one upwards; the other wheel *increases* the current without interrupting it. The connecting wires are united to the posts at the ends. Kidder has recently added, at one end of the cover, a current interrupter, and at the other a current reverser. By a simple contrivance the acid solution may be raised and lowered from the metals, so that no action may take place when the battery is in disuse. The apparatus is made of various sizes, from 40 cells to 100, according as it is designed for hospital, or office, or portable use.

A combination which is very convenient for office practice, and which, if necessary, can be taken out, is one composed of 60 elements of medium size, contained in a box two feet long and 20 inches wide. The elements are kept all the time in the acid solution; but in order to prevent corrosion, they should be kept *well amalgamated with mercury*, a quantity of which should always be kept in each element.

This combination may be used alone, or in connection with the cover and arrangement represented in Fig. 2.

It is believed that these modifications are in the direction of simplicity, since Smee's element is more readily managed than any other form that is used in electro-therapeutics. A number of batteries with large elements which have been made by Mr. Kidder on this plan, have, I believe, given full satisfaction.

The Introduction of Chocolate.—Chocolate was originally introduced into Europe from Mexico by the Spaniards in 1520. The best cocoa beans, from which it is made, are produced in some parts of South America.

Obituary.

PROF. GUNNING S. BEDFORD, A.M., M.D.,

OF NEW YORK.

This distinguished medical writer and ex-professor of obstetrics died on Monday morning, September 5th, 1870, at 3½ o'clock, in the 64th year of his age. The sad event was not entirely unexpected by his family, as he had been suffering with paralysis for a long time. His funeral was largely attended at St. Ann's Church, Eighth street, on Wednesday, September 7th. A solemn requiem mass was celebrated by Rev. Father Preston. Archbishop McCloskey, a former fellow-student of the deceased, was present, and in well-chosen words alluded to his many virtues and high medical and oratorical attainments.

Gunning S. Bedford, A.M., M.D., was born in the City of Baltimore, Md., in the year 1806. He was the nephew of the distinguished Gunning Bedford of Delaware, who was the Attorney-General and member of the Legislature of Delaware when it first became a State; the latter also being one of the framers and signers of the Constitution of the United States. His uncle was the intimate friend of Washington, by whom he was appointed Chief-Justice of Delaware, a position he held till his death in 1812. In 1825, Dr. Bedford graduated at St. Mary's College, Emmetsburg, with high honors. While at college he distinguished himself for his oratorical powers and beautiful diction, becoming renowned as a lecturer and speaker. He was unanimously chosen by his classmates as their "valedictorian."

After graduating, Dr. Bedford's first idea was to study law. With that intention he left Baltimore, with letters for Daniel Webster, intending to study law in that distinguished gentleman's office.

When actually on his way to present his letters to Mr. Webster, he accidentally met an enthusiastic acquaintance who had just commenced the study of medicine. The acquaintance persuaded him to go with him and hear an anatomical lecture by Dr. John D. Godman. They went—the lecturer's subject was an interesting one—the circulation of the blood. Dr. Bedford was charmed and carried away with the eloquence of Prof. Godman, and determined at once to give up all idea of law and commence the study of medicine. Immediately after the lecture, he went up to Dr. Godman and introduced himself, showing him his letter to Mr. Webster, and frankly acknowledging that the eloquence of the lecturer had converted him, and that henceforward he would devote his time and energies to medicine. He accordingly became the pupil of Dr. Godman, who in turn became his preceptor and friend, and who did much to advance him in his profession.

In 1829, Dr. Bedford graduated at the Rutgers Medical College. Soon afterward he married, and then visited Europe with the intention of advancing himself in his profession. He remained abroad for two years, during which time he devoted himself to his profession, visiting the hospitals and attending the different lectures and cliniques.

Shortly after his return to America in 1833, he was appointed Professor to the Charleston Medical College, being but 26 years of age.

He was next appointed Professor in the Albany Medical College. After delivering several courses of lectures at the Albany School, he resigned, and determined to visit New York, and make this city the field

for his future exertions; and on his arrival here at once commenced a most lucrative and respectable practice.

Dr. Bedford was the first to conceive the idea of founding the University Medical College in this city. He made the suggestion to the late Dr. Valentine Mott, whose valuable aid was of great assistance. The Medical College was soon established, with the following distinguished professors: Baine, Revere, Draper, Patterson, Mott, and Bedford. The school was a great success. Dr. Bedford held the chair of obstetrics until ill-health forced him to resign, which was in 1862. During his connection with the College, he established an obstetrical clinique—the first ever held in this country. It was very successful, and was of great service to those who were too poor to pay a doctor's fee.

Dr. Bedford wrote many articles for the different medical journals, but his two great works are *Diseases of Women and Children*, and the *Principles and Practice of Obstetrics*. The former has gone through ten editions, and the latter five editions. They have been translated into the French and German languages, and have been very generally adopted as the text-books in the medical colleges in this country.

His first attack of paralysis was experienced while in the midst of an active practice, and while in his carriage on his way to visit his patients. This was in 1864. He has experienced four other attacks since that time.

He leaves a wife and several children to mourn his loss. Among the latter are Drs. Frederick Bedford and Henry M. Bedford, and Judge G. S. Bedford.

Progress of Medical Science.

Syphilization.—Professor Freeman J. Bumstead M.D., of New York (*Am. Jour. Med. Sciences*), in an extended article on "Syphilization," asks, "*Is Syphilization to be recommended for general adoption?*" From what he has personally witnessed, and from the accounts of others, he believes that it is a very effective method for the treating of syphilis. He cannot say that he is fully convinced of the very small number of relapses after "syphilization" alleged by its advocates; not that their honesty is doubted, but results so favorable as this should be confirmed by others less enthusiastic, and less interested, before demanding implicit belief. Should further examination and experiment show that only twelve or fourteen persons out of every hundred infected with syphilis, and treated by repeated inoculations, ever exhibit any return of the disease, this method will have established very high claims in the treatment of syphilis, whenever circumstances will permit its being carried out, as it may be in our hospitals and other eleemosynary institutions. But, judging from what he has seen of the practice, nothing less than a very strong probability, in case he had syphilis, that the disease, if left alone, or if treated by mercury, would terminate disastrously, could induce him to undergo the personal discomfort, and for the length of time, which has been witnessed in the patients at Charity Hospital. In short, he is obliged to subscribe to the opinion expressed by Messrs. Lane and Gascoyn, that "syphilization is not a treatment which can be recommended for adoption."

A Rare Disease of the Joints.—Professor Samuel Jackson, M.D., of Philadelphia (*Am. Jour. Med. Sciences*), describes several cases of a rare form of disease resembling rheumatoid arthritis, which have fallen under his observation in the course of his practice. The peculiarity of the affection is, that it is confined to the ligamentous tissues, whilst the general health of the patient is not at all disturbed. He has not been able to find any similar form of the disease described, and when in London he consulted Sir Benjamin Brodie in regard to it, who confessed that it was entirely new to him.

Influence of Section of the Cervical Pneumogastric.—After detailing fifty-one experiments on animals, Professor Horatio C. Wood, M.D., Jr., of Philadelphia (*Am. Jour. Med. Sciences*), gives us his results as follows:—*First.* The division of the cervical pneumogastric does, in the majority of instances, but not always, absolutely arrest free gastro-intestinal secretion, emetics and cathartics being absolutely powerless to produce it. *Second.* That this arrest is not due to any direct influence which the nerve has upon the intestine or its circulation, but is owing to two or three causes: accumulation of carbonic acid in the blood, interference with the circulation of the lungs backing up the blood upon the portal circulation, and perhaps shock.

These things being granted, the opposite results obtained by Brodie and Reid are explainable. It is well known that in a small proportion of cases division of the nerves does not induce the changes in the lungs ordinarily so fatal. In such instances there is no great accumulation of carbonic acid in the blood, nor is there any backing up of the blood in the pulmonary artery, and consequently upon the right heart, and finally portal circulation.

The secondary results of section of the par vagum—the actual causes of the arrest of gastro-intestinal secretion—are therefore wanting in these cases; and he believes it to be in such that emetics and cathartics act freely after division of the nerves. The rarity of such cases is the reason why those experiments are proportionately so few in which such drugs act in their ordinary manner after the operation.

Acetic Ether as an Anæsthetic.—At a recent meeting of the College of Physicians, Philadelphia, Dr. H. C. Wood (*Am. Jour. Med. Sciences*) spoke of the prevalent dissatisfaction of the profession with our present anæsthetics, and the consequent search, especially in London, for new ones. He exhibited a specimen of *acetic ether* to the College, prepared for him by Mr. Chas. Bullock, of Philadelphia, and stated that he had not yet tried to fully anæsthetize the human subject, but in pigeons and rabbits it produced perfect unconsciousness without nearly so much previous struggling as when ether was used. It has a peculiar pleasant odor, very closely resembling that of apples, which no doubt owe their smell to it or the closely allied malic ether. An advantage which it has over sulphuric ether, especially for night use, is its comparative non-inflammability, connected partly with its lesser volatility. A pigeon passes gently into an insensible state, and awakes without struggling after a few minutes of quiet sleep.

Functional Dyspepsia.—Dr. Geo. P. Andrews, of Detroit, Mich. (*Detroit Review of Medicine and Pharmacy*), insists upon rest to the stomach, in this affection, and the avoidance of food difficult of digestion or in excessive quantities. The milk diet is often attended by the happiest results. It may be taken clear or with one-third of lime-water, and in small quantities often. Strict attention to hygienic matters must be enjoined, and no alcoholic stimulants allowed, except as directed by the physician. Usually, little medication will be needed, except to relieve torpor of

the bowels, which should be accomplished by the mildest laxatives, when enemata are insufficient. Pain may be allayed by the various narcotics, bismuth, hydrocyanic acid, or carbolic acid exhibited in one or two drop doses suspended in mucilage, repeated every three or four hours. This latter remedy will also, usually, allay nausea and vomiting.

ADDISON'S DISEASE.—Dr. Gordon (*Med. Times & Gazette*), while alluding to the exact relationship between bronzing of the skin and supra-renal disease—which are open questions—remarked that there is reason to believe that Dr. Addison was aware that the connection between the two conditions was not invariably found to exist. The most frequent morbid appearance in the supra-renal capsules, when disease of those organs is discovered, in cases of bronzing is "tubercular" deposit. So far as observations have yet gone no connection has been traced between bronzed skin and disease of any other of the ductless glands.

RHEUMATISM.—J. Parker, M.D. (*Eclectic Med. Jour.*), finds the following excellent in chronic rheumatism:

℞. Comp. syr. stillingia, ℥ iij.
Vin. rad. colchicum, ℥ iss.

MIX.—Dose—A teaspoonful thrice daily, and alternate with carbonate of lithia.

EXOPHTHALMIC GOITRE, WITH INSANITY.—J. B. Andrews, M.D. (*Am. Journal of Insanity*), in an interesting communication on this subject, first describes the disease as follows:—It has three characteristic symptoms: prominence of the eyeballs; enlargement of the thyroid gland; palpitation of the heart. There is generally no disturbance of vision. Occasionally adaptation is difficult, and then weakness of sight; but diplopia is never present. Hypertrophy of the thyroid gland takes place gradually; both lobes may be enlarged to an equal degree, but in a majority of cases the right is the one chiefly affected. The patient complains of dizziness and palpitation of the heart long before the exophthalmos or the goitre have been detected. The force of the heart's action at times produces a prominence of the chest walls which can be readily detected. There are secondary symptoms which should be noted. In some cases the appetite is diminished, in others voracious and always capricious. The heart's action is increased in frequency, the pulse varying from 120 to 150. Vomiting and cough are unpleasant, and, at times, dangerous complications of the disease. The patient's temper is greatly altered. He may become quick-tempered, irritable, and at times violent. Hallucinations and sometimes insanity may occur in the course of the disease. A change in the voice takes place, which is due to disturbance of respiration from pressure upon the recurrent laryngeal nerve. Patients rally from several of these attacks, and may die of intercurrent disease. Death in the first paroxysm is not frequent. When the prominence of the eye shows itself, as it often does, in paroxysms, this condition is ascribed to a violent and active congestion. The only other disease with which this is likely to be confounded is aneurism of the aorta, or of one of the arteriæ innominatæ. In aneurisms the swelling will occupy but one side of the thyroid gland: in this disease it may exist on both sides. Graves' disease is common among women, but relatively rare in men. Of fifty cases collected by one author, but eight occurred in men. Dr. Andrews alludes to the fatal case of a man, twenty-six years of age, which came under his own observation, and to three cases reported by Dr. Morell Mackenzie—the latter being women. The treatment adopted in the first was that recommended by Trousseau—the free use of digitalis and the local application of the ice-bag. The digitalis quiets palpitation and diminishes the frequency of the cardiac and arterial pulsations; the application of the ice offers the twofold advantage of causing a violent revulsion to the skin, and of rendering innervation and nutrition more perfect. Bleeding is recommended only when the pressure of the gland from congestion threatens asphyxia. Dr. W. B. Cheadle has recently reported to the Harverian Society eight cases of this disease, in six of which iodine was given continuously for many weeks, and in only one case was it deemed necessary to discontinue it on account of increased palpitation following its administration.

HYDRATE OF CHLORAL IN DELIRIUM TREMENS.—C. A. Stivers, M.D., of the San Francisco Hospital (*Pacific Med. and Surg. Journal*), commends this remedy in severe attacks of delirium tremens, and publishes two cases. In the first case, female, æt. 38, native of Ireland, the nurse was obliged to place her in a strait-jacket. Dr. S. ordered: ℞ Chloral hydrate, 1 dr.; syr. pruni virg., aquæ, each, 1 oz.; one-half to be taken at once, and the remainder in two hours, if no sleep. The first dose was given at 10 A.M., the second at 12 M. No sleep, but patient rather more quiet. Repeated the same prescription, and gave one-half at 2 P.M. Patient sleeping soundly at 2½ P.M., and continued in that condition until 9 P.M., when she awoke free from delirium. Took a pint of beef-tea. At 12 M. the remainder of the hydrate was given—in all 2 dr. Directly afterward she fell asleep, and so continued until morning, when she was discharged cured. No return of delirium occurred.

In the second case, male, æt. 27, native of Ireland, only two doses were given. After the first dose the patient slept two hours. The remainder being given, he was asleep in ten minutes, and continued in a sound sleep all the afternoon and night—a little over fifteen hours. Next day he was discharged cured.

He adds, in concluding: "In some instances in which it has failed to exhibit its effects, undoubtedly the failure was owing to the smallness of the dose." In his cases the chloral was given in full doses.

TWO CASES OF CHOPART'S OPERATION.—Daniel Leasure, M.D., of Alleghany City, Pa. (*Med. and Surg. Reporter*), alludes to two satisfactory operations of this nature, made by him for the purpose of adding to the statistics of the conservative surgery of the foot, in which the surgeon might have justified himself against blame by amputation in the lower third of the leg, but the patients would not have been by any means quite so well off as they are.

GALVANO-PUNCTURE.—The discovery of this branch of surgical treatment originated in the brain of M. Pravaz, of Milan, in the year 1832. It fell into neglect until Liston, in the year 1838, and M. Petrequin of Paris, advocated its use again in the treatment of aneurisms.

This operation is fully considered by Allan McLane Hamilton, M.D., in his graduating thesis entitled "Galvano-Puncture applied to the Treatment of Aneurisms," which took the "first Thesis Prize" of the Class of 1870, College of Physicians and Surgeons, New York. He reports 90 cases of aneurisms treated by galvano-puncture; cured, 48; not cured, 42.

Dr. H. would suggest its use in pelvic hæmatocele and in fungus hæmatoides. For the former operation he has devised an instrument consisting of two parts, a *rectal* and *vaginal*. The rectal forms the negative electrode, the vaginal a positive.

Dr. Bocchetti reports a case in *l'Union Médicale*, of the agency of this remarkable power in extra-uterine fœtation.

SUPERNUMERARY FINGERS AND TOES.—A young man belonging to the literary department of the University of Michigan, recently presented himself to Prof. A. B. Crosby, M.D., who amputated a supernumerary little finger from the ulnar border of the left hand. On the right hand he had five symmetrical fingers besides the thumb. He has also six symmetrical toes on one foot. These peculiarities are evidently hereditary. The father had six toes on each foot, and six fingers on each hand. He has one brother who has the same number of supernumeraries as the father; and a second brother has six toes on each foot, and six fingers on one hand. A niece, child of the patient's brother, had six fingers on each hand, and six toes on each foot.—*Mich. Univ. Med. Journal.*

THE ABORTIVE TREATMENT OF URETHRITIS.—Dr. Alex. W. Stein, of New York (*N. Y. Med. Journal*), in a paper on "Pathology and Treatment of Urethritis," says he has very little to do with the abortive treatment of urethritis, for the following reasons: 1st. Because it is extremely seldom that he sees his patients when such a treatment is justifiable. 2d. That when the opportunity offers it very frequently fails in its object. 3d. When it fails, it intensifies and prolongs the disease; and 4th. Because of the danger of producing a good deal of mischief. Furthermore, it is not improbable that many of the cases reported as successful instances of this practice would have recovered without going through the painful ordeal of caustic injections. Slight irritation at the meatus with a little mucous discharge is not an unfrequent consequence upon excessive sexual intercourse, which usually disappears within 36 hours under a very mild treatment, often with no interference whatever. These slight symptoms, therefore, cannot always be regarded as indicating abortive measures.

Of all remedies, the argenti nitras is least adapted for injection into the urethra. If a strong solution of this caustic is applied, it frequently excites violent inflammation.

HEALTH RESTORED BY THE EXTRACTION OF DISEASED TEETH.—James H. Hodgkin, D.D.S., Alexandria, Va. (*Am. Jour. of Dental Science*), alludes to the case of a woman, æt. thirty-eight, who came to him with distressing pains in the head, affected sight, and impaired hearing, for the purpose of having the upper teeth extracted, which were badly decayed, being mere stumps. All of the teeth were extracted, with the exception of two, and she was requested to call in about three weeks, when they would probably be in a better condition and her nerves more firm. She called at the time appointed, and expressed herself much gratified, as her troubles were much mitigated, hearing and sight improved, and the distressing pain in the head almost gone. The remaining roots were now removed, and she decided to wait until she could have a permanent set of teeth before having the plate constructed. At the appointed time the patient called to have the artificial teeth constructed, and stated that the restoration of her health was entire, and has been since, a period of two years.

HYDROPHOBIA.—M. H. Pouley, in a valuable contribution to the *Académie des Sciences*, on the causes and management of hydrophobia, declared that it was possible to obviate the effects of the inoculation of virus of rabies by a prompt cauterization of the bites.

Of 310 cases of bites alluded to, 284 were inflicted by male dogs, 26 by bitches, 5 by cats, and 5 by wolves. The cases in winter corresponded almost to a unit with the hottest period of the year.

SCHWANN'S DISCOVERY.—In 1837 Schwann discovered that meat highly heated and excluded from air never putrefied.

URINARY ANALYSIS.—A fact recently published by Dr. Thudichum is calculated to throw some degree of doubt on the accuracy of the urea-determination by the well-known method of Liebig—a method which consists in the employment of a solution of nitrate of mercury of known strength.

It appears that, in addition to the compound of urea with oxide of mercury, there is formed the mercury-salt of a new organic acid, which its discoverer, Dr. Thudichum, has called "kryptophanic acid," and to which the following formula is assigned: $C_{10}\ H_{18}\ N_2\ O_{10}$.

The salts of the new acid are, for the most part, soluble in water, and of three kinds—to wit, mono-, di-, and tri-basic. The lead, silver, and mercury salts are insoluble in water.—*Lancet.*

IODOFORM.—Dr. Stiles Kennedy, of Newark, Del. (*The Med. and Surg. Reporter*), recommends iodoform as an addition to the ordinary plasters and ointments for syphilitic periostitis. An ointment containing from 30 to 60 grains of iodoform to an ounce of lard is a beneficial remedy to painful burns, sores, chancres, and boils, promoting rapid healing. In two cases of chancre the dry powder was applied with magical results.

LOTION OF LEMON-JUICE.—Take of fresh lemon-juice, rose-water, alcohol, equal parts—mix. The next day decant the clear portion, and strain it through muslin.

ON TEMPERATURE IN SO-CALLED MILK-FEVER.—Dr. D. F. Lincoln, of Boston (*Boston Med. and Surg. Journal*), gives the subjoined statements made recently by Prof. Halbertsma, of Utrecht, as the results of measurements of temperature, taken twice or oftener every day, in 134 cases of lying-in women. 1st. We have no right to connect the sub-febrile elevations of temperature (Wunderlich), on the 3d and 4th day after delivery, with the secretion of milk exclusively. The processes which take place in the genitals have certainly a great influence; probably the greatest. 2d. Febrile *temperatures* (which alone give us the right to speak of *fever*) are usually the result of traumatic fever, or of the fever of infection. 3d. We have at present no right to suppose the existence of such a thing as "milk-fever"—unless, with Schröder, the name is reserved for the non-purulent inflammations; a nomenclature which is not in harmony with that employed in inflammations of all other organs. We should have, in consistence with this system, to speak of lymph-fever, prior to the occurrence of suppuration in the glands; while lymphadenitis would have to be reserved for the actual suppurative stage.

METHYL-ETHYLIC ETHER AS AN ANÆSTHETIC FOR SHORT OPERATIONS.—Benjamin W. Richardson, M.D., of London (*Med. Press and Circ.*), at a late meeting of the London Medical Society, suggested *methyl-ethylic ether*, as the readiest and best agent for short operations. It was better than nitrous oxide gas, because it allowed air to be given with it, and did not asphyxiate; it was better than bichloride of methylen, because it did not produce muscular spasm and syncope. At the same time he did not consider it as perfect, nor should he consider general anæsthesia perfected, until he or some other observer should discover an agent that will destroy sensibility

without interfering at all with organic muscular life, voluntional power, or consciousness. Methylic ether approached this perfection, though it did not touch it, and it encouraged perseverance in experimental research. For these reasons it was worthy the attention of the profession.

HYDRATE OF CHLORAL.—Dr. Miller, of Stockbridge, Mass. (*Boston Med. and Surg. Journal*), reports the case of a clergyman, 54 years of age, who, 13 years ago, received a severe blow upon the cranium and has ever since been subject to attacks of pain on the left side of the head. He has greatly improved under hydrate of chloral in ten-grain doses, given when the attack is anticipated.

A FLUID FOR PRESERVING ANATOMICAL SPECIMENS.—Dr. C. Méhu, Pharmacist to Necker Hospital, Paris (*Bull. Gén. de Thérap.*), recommends the subjoined formula as a preserving fluid:—

Arsenious Acid	20	parts.
Crystallized Carbolic Acid	10	"
Alcohol	300	"
Distilled Water	700	"

ARTIFICIAL FECUNDATION.—Dr. Girault, of Paris (*Medical and Surgical Reporter*), lately read an essay before the Medical Society of the Pantheon, entitled "A Study on Artificial Generation in the Human Race," and reported in all twenty-seven attempts at artificial procreation in the human female, of which ten were successful, and others doubtless would have been, if the couples had been more persevering in their efforts, and allowed him to continue his endeavors.

The only instrument necessary is a uterine catheter with a funnel-shaped opening at the external end. Into this the sperm is placed, after the point has been introduced into the cervical canal, and blown into the cavity of the uterus. The instrument should be of the temperature of the body, and the semen contain active spermatozoa, with long and rapidly vibrating tails, as the latter is the sign of their fecundating power.

Among others, he related the following case: A man, 65 years old, married to a wife of 27 years, had passed seven years without offspring. The pair applied to Dr. Girault, who, after four failures, succeeded so completely on the fifth attempt, that in nine months afterwards the lady was delivered of a pair of twins, one boy and one girl. The latter died after three months, but the former survived and was healthy when last seen, at the age of nine years.

POISONING BY AMERICAN CICUTA.—Four cases of poisoning occurring in children, three of which were fatal, from eating the root of the Water Hemlock or American Cicuta, are related by Dr. W. H. Matchett, of Greenville, Ohio (*Cin. Lancet and Observer*). He has no knowledge of the poisoning of animals by this plant; many rumors, however, are afloat of sheep and cattle being killed by it. In early days of the settlement of Ohio the "milk sick" was a dreaded disease, and many are of the opinion this plant was the poisonous agent; but for some years past there have been no cases of milk sickness, yet the cicuta is now found growing in the low or marshy pastures.

TREATMENT OF TUBERCULOSIS.—Wade Minor Logan, M.D., of Cincinnati, Ohio (*Cin. Lancet and Observer*), considering alcoholic stimulants in the treatment of tuberculosis as being worse than useless, except in cases of extreme exhaustion, suggests the use of nitric and muriatic acids. Nitric acid is tonic and antiseptic, having been successfully used in typhus and malarial fevers. Muriatic acid is tonic, antiseptic, antiphosphatic, and cholagogue, and is used as an adjuvant to the former acid.

Dr. Logan administers nitric acid in doses of gtt. xv. of the officinal diluted in *aquæ puræ* ʒ ij., immediately after each meal, for the purpose of aiding digestion. The quantity of muriatic acid which he administers is contained in gtt. xxx. vel gtt. xv. of Tr. ferri chloridi, giving this agent for the two-fold purpose of both the acid and iron, having it taken sufficiently diluted half an hour before each meal, thereby exerting its stimulating or appetizing influence. In support of his views, a tabulated report of 14 cases is appended; 6 of these recovered; 4 are recovering; 2 died; 1 is favorable, and the other is put down "stationary."

These cases were treated with the acids, aided by various auxiliaries, as counter-irritants, narcotics, expectorants, cod-liver oil where it was tolerated, using very little alcohol, however.

SACCHARINE DIABETES.—Two cases of this disease are narrated by J. S. Cabell, M.D., Prof. of Physiology and Surgery, University of Virginia (*The Richmond and Louisville Med. Journal*), which were benefited by the administration of Rockbridge alum-water, and a restricted diet, consisting of bran cakes made according to the formula of Dr. Camplin, of London, of fresh meat and of vegetables which contain little or no sugar or starch.

In the first case, Prof. Cabell was struck with the apparent effect of the Rockbridge alum-water, which had been suggested by a member of the patient's family, and ordered it to be continued. He had often experienced in his own person the marked effect of this mineral water in allaying thirst with a very trifling consumption of the article, and advised it in the second case. These cases are given to the profession with the view of inviting attention to a remedy which is believed to have been an efficient agent in the apparent cure of the second case, and in relieving, in a marked degree, the other case in which the remedy was used in a very irregular manner.

USE OF MILK AS PRESERVATIVE AGAINST LEAD POISONING.—M. Didierjean, a red-lead manufacturer (*The American Chemist*), states that, having taken all possible precautions to keep their workmen in a healthy state, he did not, however, quite succeed in preventing lead colics until, by a mere accident, it was found that two of their men were never affected at all. On inquiry being made, it turned out that they regularly took milk as drink at the time of taking their meals at their works. The owners of the works were thus induced to make the use of milk (one litre daily) obligatory for their workmen while at the works; and, by exercising a proper surveillance, have succeeded, during 18 months, of keeping, by this means, all their men free from any symptom of lead disease.

NEURALGIA OF THE OCCIPITO-FRONTALIS MUSCLE RELIEVED BY AN OPERATION.—John O. Mettauer, M.D., LL.D., Prince Edward Court-House, Va. (*The Boston Med. and Sur. Journal*), advocates, in stubborn cases of neuralgia of the occipito-frontalis muscle, the subcutaneous division of the occipito-frontalis muscle. The muscle is divided by four incisions, without removing any portion of the hair, through a single scalp-wound. In six days these incisions heal perfectly, and with no more than the requisite degree of traumatic inflammation. He has treated successfully by incision two cases of this character, which had resisted the free use of quinine and narcotics.

Medical Items and News.

A Private Asylum for Inebriates and Opium-Eaters.—A new institution of this character has been established at Greenwood, Mass., eight miles from Boston, by Dr. Albert Day, late of the Binghamton Inebriate Asylum.

Female Medical Students in Germany.—The University of Vienna admits women to its Medical School. Two females have already entered.

British Medical Association.—The Thirty-eighth Annual Meeting of the British Medical Association was held in Newcastle-upon-Tyne, on the 9th, 10th, 11th, and 12th of August. An *Address in Medicine* was delivered by Francis Sibsom, M.D., F.R.S., F.R.C.P., Physician to St. Mary's Hospital. An *Address in Surgery* was delivered by G. A. Heath, M.D., M.R.C.S., Senior Surgeon to the Newcastle-upon-Tyne Infirmary.

No paper presented in the sessions occupied more than *twenty* minutes in delivery—all subsequent speakers did not exceed *ten* minutes.

Exophthalmic Goitre.—This disease was first described by Graves in his treatise on "Clinical Medicine." It has also been called Basedow's disease, but his description was subsequent to Graves.

The Surviving Graduates of Yale College.—From the "Obituary Record of Graduates of Yale College," we find that the whole number of deaths reported as occurring during the last year, ending in July, 1870, is 66, and the average age of the graduates of the Academical Department is 61 years.

The surviving graduates of the last century are, as for two years past—Class of 1794, Hon. Ezekiel Bacon, Utica, New York, born 1st September, 1776; Class of 1796, Timothy Bishop, New Haven, Connecticut, born 29th October, 1777; Class of 1797, Rev. Charles Goodrich, Penn Yan, New York, born 2d April, 1778; Class of 1800, Rev. Thomas Williams, Providence, Rhode Island, born November, 1779.

Icterus Neonatorum.—S. M. Monser, M.D., of San Francisco, California (*Cal. Med. Gazette*), asserts that a young Scotch woman in San Francisco was delivered of three male children with icterus neonatorum, born in succession of the same parentage. The first, born eight years ago, died at birth; the second succumbed on the ninth day; the third died on the eleventh day.

He has no doubt that phlebitis (perhaps of the portal vein) was the cause of death in all these children; but why it should have occurred is a question he is not prepared to decide. The parents both seem to enjoy perfect health.

Long Island College Hospital.—Professor Alpheus B. Crosby, of the University of Vermont, has accepted the chair of surgery in the Long Island College Hospital, of Brooklyn, New York.

Japanese Professorships.—The King of Prussia has been requested by the Japanese Government to send out competent German medical men to fill medical and surgical professorships.

A New Anæsthetic.—Dr. Liebreich, of Berlin, claims that he has discovered a substitute for chloroform, which he calls æthyliden chloride.

Hudson County, New Jersey, Hospital.—This hospital was formally opened June 2d. The following is the medical staff: *Consulting Surgeons*, Professor A. C. Post and Dr. J. H. Hinton, New York. *Consulting Physicians*, Drs. H. D. Bulkley, New York, and J. M. Corneilison, Jersey City. *Attending Physicians and Surgeons*, Drs. I. N. Quinby, F. E. Noble, E. P. Buffit, J. B. Burdett, John M. Julian, L. W. Elder, John Kudlick. *House Physician and Surgeon*, Dr. John Q. Bird.

Iodide of Potassium in Consumption.—Dr. Batchazer Foster (*Med. & Surg. Reporter*) recommends iodide of potassium in some cases of phthisis. He only gives it in doses of eight to fifteen grains, however, when ether is not tolerated with cod liver-oil.

A Gift to the Massachusetts General Hospital.—Dr. Henry J. Bigelow, the senior surgeon of this venerable hospital, has given it a complete set of surgical instruments, made expressly under his direction in London and Paris. In addition, Dr. Bigelow presents a permanent fund for their renewal, and subscribes for a *free bed* for five years, the whole donation amounting to the sum of five thousand dollars.

Hartford Retreat for the Insane.—We glean the following from the Forty-fifth and Forty-sixth Annual Reports of this Institution:—The whole number of patients in the Retreat at the beginning of the year, commencing April 30, 1869, was 135; admitted during the year, 123; total in year, 258. Of this number there have been discharged: Recovered, 41; much improved, 16; improved, 32; not improved, 10; died, 25; total discharged, 124. Remaining in Retreat, April 1, 1870, 134; whole number admitted to April 1, 1870, 5,150; whole number discharged during same period, 5,016; whole number remaining, 134. Of those that died during the past year, 14 were males and 11 were females; 9 deaths were from general paralysis, 7 from acute mania, 3 from chronic mania, 2 from puerperal mania, 2 from apoplexy, 1 from epilepsy, and 1 from rheumatic fever.

The Heart's Labor.—In a boat race, it is calculated that fifteen foot-pounds of work are performed by each ounce of muscle during each minute of the rowing. No muscular labor that man can undertake is more severe than this; and yet this labor is only three-fourths of that which is exerted day and night during life by each of our hearts. If the heart should expend its entire force in lifting its own weight vertically, it could raise that weight 19,754 feet in an hour.—*Boston Jour. of Chem.*

The Waste of Croton Water.—The Water Purveyor in the New York Department of Public Works estimates that fully fifty million gallons of water are daily wasted in the city, the greater portion being at piers and ferries. Water meters are being prepared, and will speedily be adjusted at all those places where there is reason to suspect any waste.

Mercurial Suppositories in Constitutional Syphilis.—Prof. Lebert (*Berlin Klin. Wochenschrift*) has had such success in the employment of these suppositories that he is desirous of calling attention to their value.

They are formed by mixing mercurial ointment with butter of cocoa and white wax, so as to obtain a convenient consistence.

Treatment of Carbuncle by Pressure.—Dr. M. L. Bennett, of Burdett, N. Y. (*Am. Jour. Med. Sciences*), advocates this mode of treating carbuncle, as recommended by Dr. O'Ferral, of Dublin, Dr. John Ashhurst, Jr., of the Episcopal Hospital, and others.

Oxygen Gas in Sun-Stroke.—Dr. C. G. Hill, Resident Physician at Washington University, Baltimore (*The Medical Bulletin*), has employed inhalations of oxygen gas in sun-stroke, with good results.

Sugar Consumed in the United States and Great Britain.—The amount of sugar consumed in the United States during the year 1859 was 431,184 tons, or about 30 lbs. per head.

The average increase of its use during the decade ending 31st December, 1859, was 6¾ per cent. per annum, which would give in round numbers 990,000 tons, or nearly 50 lbs. per head, as the amount consumed in 1869. In Great Britain, in 1869, the amount consumed was 586,954 tons, or an average of 43 lbs. per annum for each individual; while in Russia the yearly consumption does not exceed 3 or 4 lbs. per haad.

The Discoverer of the Acarus in Sugar.—Dr. Hassall was the first to employ the microscope in his researches into the adulteration of sugar, and discovered a beetle-like animalcule, of the genus *Acarus*, approaching somewhat in its organization the *itch-mite*.

Ice.—London (England), with a population more than thirteen times larger than that of Boston, Mass., consumes one-half the quantity of ice.

California Quicksilver.—The total annual supply of quicksilver from California is not far from 50,000 flasks, or about 3,000,000 pounds.

Death of English Physicians and Surgeons.—Charles Hewitt Moore, F.R.C.S., author of several important papers in the "*Medico-Chirurgical Transactions*," died June 6th, æt. 49.

Edwin Lee, M.D., the well-known author of Baths and Watering-places of the Continent and England, was stricken down in June, and died shortly afterwards.

Daniel Maclachlan, M.D., Retired Physician and Surgeon of the Chelsea Hospital, passed away June 15, æt. 63.

Exsection of the Ulna.—On the 25th of February last, Dr. C. S. Muscroft, M.D., of Cincinnati, Ohio (*The Cin. Lancet and Observer*), successfully exsected the entire right ulna from a carpenter, æt. 42, with caries of the bone. No vessel required to be tied. Before closing the wound it was well washed out with a solution of carbolic acid. His confinement to bed lasted three weeks. With the exception of anchylosis of the elbow-joint, the arm now (July 1st) is nearly as useful as it was previous to the injury which led to the exsection. There is, he thinks, some reproduction of the ulna, commencing at the elbow-joint and extending about three inches towards the hand.

Fatty Liver.—This variety of diseased liver is almost peculiar to phthisis. In three years Louis met with it forty-nine times, and forty-seven of the patients died phthisical.

Crossly.—Sir Francis Crossly, an English millionnaire, has given £200,000 to certain medical charities, with the singular condition that it shall be perpetually invested in United States securities.

Medical and Chirurgical Faculty of Maryland.—At the annual convention of this society, held April 20th and 21st, at the Hall of the Faculty, in Baltimore, the following officers were elected: President, Prof. Nathan R. Smith; Recording Secretary, Dr. H. M. Wilson; Assistant Secretary, Dr. G. W. Register; Corresponding Secretary, Dr. E. Lloyd Howard; Treasurer, Dr. P. Kinnemon.

The Siamese Twins.—This renowned pair—called Chang and Eng—who have recently returned from the Old World in the steamer Palmyra, are in a sad plight. One has had an attack of hemiplegia. The other seems to be perfectly well. The question is suggested—Should the paralytic die, what would be the fate of the other, since science has determined that they cannot safely be separated by a surgical operation? They have left this city for their farm in North Carolina.

Death of an English Workhouse Woman—A Hair Eater.—A woman named Harriet Adams lately died in St. Pancras Workhouse Infirmary, from the effects of eating her own hair. Dr. Ellis, on making a post-mortem examination of the body, found embedded in the stomach and intestines a quantity of human hair—no doubt her own—and wool, which the deceased had eaten. The effect of the secretion of this hair and wool had been to produce ulceration of the stomach, and cause death.

Death of a Noted English Ophthalmologist.—John Zachariah Lawrence, F.R.C.S., M.D., a renowned writer on ophthalmology, died July 18th, in the 42d year of his age.

A Diminutive Child.—Mrs. James Harris, of Jefferson County, Ill., has a lively four-months old baby that weighs only two pounds.

Decease of an ex-Professor.—Dr. Leonard Marsh, for fifteen years a Professor in the University of Vermont, died August 16th.

Malformation—Absence of the Right Lung.—Dr W. Dickey (*Cin. Lancet and Observer*) publishes a case of this character occurring in a pale phthisical girl of 16 years. The lung of the left side was somewhat larger than normal; no lung in the right side, not even a segment at the bifurcation.

The Removal of an Immense Tumor from the Head.—John P. Furniss, M.D., of Selma, Ala. (*N. O. Journal of Medicine*), recently removed from the head of a negro girl, aged 13, a fibro-cystic tumor which weighed eight pounds and seven and a half ounces (avoirdupois). It extended from the anterior fontanelle to the occipital protuberance, and strongly adhered to the bones of the head. The patient did well until the sixth day, when erysipelas set in, and on the eighth she died.

Decease of a Western Ophthalmologist.—Dr. J. S. Haldreth, a well-known ophthalmologist of Chicago, Ill., died suddenly July 22d from an overdose of some narcotic, accidentally taken while suffering from neuralgia.

Hæmoptysis in Connection with Tuberculosis.—According to Prof. Skoda, of Vienna, hæmoptysis is *no cause* of the subsequent disease of the lungs; that cause lies somewhere else than in hæmoptysis, which is only a symptom of the diseased process in the further development of tuberculosis.

The Temperature of Baths.—Cold baths, 32° to 60° F.; cool baths, 60° to 75°; moderately tepid baths, 75° to 85°; tepid baths, 85° to 92°; warm baths, 92° to 98°; hot baths, 98° to 112°.

To Remove Silver Stains.—Wash the spots with a concentrated solution of sulphate or chloride of zinc, and rub the worst places with metallic zinc. Then rinse in pure water and complete the washing with soap. Ink stains can be removed in this way.—*Jour. of Applied Chemistry.*

Original Lectures.

ANTIPHLOGISTIC TREATMENT IN DISEASES OF CHILDREN:

REMARKS BEFORE THE NEW YORK MEDICAL JOURNAL ASSOCIATION, APRIL 15 AND 22, AND MAY 27, 1870.

By A. JACOBI, M.D.,

CLINICAL PROFESSOR OF DISEASES OF CHILDREN, COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

Lecture III. Part I.

[Phonographically reported for the Record.]

Mr. President—At the meeting of the 15th of April I stated my ideas upon inflammation and the action of antiphlogistics, which I need not repeat. I have, to-night, simply to continue my remarks upon those antiphlogistics most used in the diseases of children; and I would say again that, as the facts I have to give are mostly derived from my clinical experience, they should not be expected to cover the subject completely.

ERGOT.

The remedy that will first claim our attention to-night is ergot. If there be any doubt that quinine acts through the nervous system—and there are some who think it acts simply through a change worked in the blood—there can be no such doubt concerning ergot. Partly from the physiological experiments of Brown-Séquard, and partly from clinical observation, it must now be considered a fixed fact that ergot acts through the nervous system, and especially through the sympathetic, upon the unstriped muscular tissue under its control. Thus it is that ergot produces its peculiar effect upon the muscular tissue of the uterus, the unstriped fibres of the bladder, the muscular layers of the intestines, and especially upon the muscular coat of the blood-vessels. Its power in diminishing the size of the blood-vessels is manifest from its value as a hæmostatic; and it is of this power we have to speak in considering its antiphlogistic effect.

This effect is noticeable in fevers generally, and particularly in fevers of the intermittent type. It is an established fact, in my opinion, that many cases of obstinate intermittent fever will, when no longer benefited by quinine or arsenic, still be benefited by the action of ergot. My first experience with the drug as an antifebrile was in cases of this nature—in very obstinate intermittents which yielded to this after other remedies had been proved powerless. From that time—about a dozen years ago—I have given it not only in intermittent fevers, but in a number of other affections, chiefly the following:

In many cases, not uncommon in women and children, of spinal meningitis—resulting in pain in the spine, slight fever, occasional convulsions, partial or total paralysis—I have given a mild preparation of ergot, and have uniformly found a beneficial effect.

I have given ergot in the first stage of the so-called infantile paralysis, or, as I incline to call it in most cases, the spinal paralysis of children. For I take it that the great majority of instances of "infantile," or "dental" paralysis are dependent upon congestion of the spinal cord, that is, dilatation of the blood-vessels, and usually with hemorrhage taking place to a small extent inside the vertebral canal. It usually happens that such children are paralyzed in one lower extremity, or in both; now and then also in an upper extremity; sometimes without premonitory symptoms, sometimes with prodromic fever, severe or slight, etc. These symptoms are, to my mind, best explained, in most cases, by supposing an extravasation with the attendant dilatation of blood-vessels. The common observation is, that such cases often begin to improve immediately after the affection has set in; improve very rapidly for four, five, or six days; improve slowly for five or six weeks more; and then the process stops, no benefit being derived from any treatment, except, perhaps, from the electrical. As, in my view, the pathology includes dilatation of the blood-vessels in the neighborhood of the seat of hemorrhage, not only producing the effects of congestion, but also incurring the liability to further extravasation, I give ergot to contract the vessels, and I have uniformly seen that in such cases as came under this treatment, even so late as the second or third week, the improvement was much more rapid than in those where nothing was done. But many of the cases we do not see at all until it is too late to do anything.

In several cases of chorea minor, or St. Vitus' dance, I have used ergot with great benefit—not in the form dependent on rheumatic affection and found in the course of slight articular rheumatism, but in that form which goes hand in hand with pain in some portion of the spinal column, and can be traced back to spinal meningitis.

Now and then we have neuralgic affections depending upon spinal meningitis, which will be helped by ergot, if given early, at the same time that slight purgatives, etc., are not omitted—all those cases of pain in the back with, perhaps, slight intercostal neuralgia, perhaps slight herpes zoster, which are not improved by the usual treatment, but require something to act upon the blood-vessels.

I have tried ergot also in some cases of brain disease, but cannot say that I have been so successful there; at all events, I cannot lay my finger upon such a number of successes as I am confident that I have gained from this remedy in diseases of the spinal canal. In diseases of other organs I have had very little experience with it, and so am not prepared to recommend it so highly as I have done in the cases mentioned.

The only preparations of ergot which I have used to any great extent are the *ergotine*, so-called, of Bonjean,—a French preparation in solid-extract form, which makes a good pill mass,—and the fluid extract prepared by Dr. Squibb. I have been so well satisfied with these two preparations that of late I have used no other; though before Squibb's fluid extract came into market I employed a decoction in water, with the addition of a little sulphuric acid. The doses should be much larger than those prescribed in the books. I have seldom seen much effect from the usual doses, but I seldom miss the desired effect from the larger ones. In a case of spinal meningitis in a child two or three years of age, I would give *at least* two drachms of Squibb's fluid extract in the day, or from four to seven grains of Bonjean's ergotine. Where its use is to be long continued, for chronic hemorrhages, etc., I give commonly about a scruple of the ergotine, daily, to an adult: and to a child in proportion to age; though, as I have before stated, I think that of febrifuges the proportionate dose for children is much larger than given in the books. None of the symptoms of so-called ergotism, whether of the spasmodic or of the gangrenous form, have I seen. I do not believe that ergotism, as it has been described by the older writers, will be found in our country and among a population like ours. The symptoms of spasm, and especially of gangrene so fearful and fatal, were observed in a population starved for years, in countries where the only food was rye; and when

the rye was chiefly ergot, the people had nothing to supply their want. Under such conditions gangrenous ergotism is possible. But here, in a population living on milk, meat, etc., it is impossible as a result of the employment of ergot as a remedy. I have seen no untoward effects from its use; and there is no other remedy that I rely upon with such confidence, in the affections I have pointed out, as upon this.

ALCOHOL.

I have now to speak of another remedy, of much importance, which has not until quite recently been counted among the antiphlogistics—alcohol. It certainly deserves the name of an antiphlogistic, as I propose to show. Like other stimulants—musk, camphor, ammonia, etc.—it has been used in inflammations by Braun and his school. It was perfectly natural that they should employ it thus, because, in their opinion, every inflammation was due to an adynamic condition of the system. The first to use it as a direct febrifuge was Todd, who found that under brandy or strong port wine the pulse became less frequent and the temperature of the body was lowered. True, he did not test the temperature by the thermometer, and so was perhaps less able to judge of it than are we at present. He thought also that alcohol acted as nutriment; and Anstie, as you know, holds the same opinion. Drysdale considered that it passed through the system unchanged, and therefore could not act as nutriment. He regarded it as a stimulant proper, and nothing else.

Since the time of Todd, alcohol has been used in many forms of fever and inflammatory disease. Murchison, regarding it as a very volatile stimulant, gives it in cases of paralysis, particularly paralysis dependent on functional weakness of the nervous centres. He thinks it acts especially upon that portion of the nervous system which serves as the inhibitory centre of circulation and temperature; and that by its aid, without other treatment, many diseases will run through their full course and leave the system unharmed. While Murchison was stating these opinions, a few years ago, Richards was discovering that alcohol lowered the bodily temperature as tested by the thermometer. In our experiments upon this subject, we must not confound the effects of wine with those of brandy. In the latter we have alcohol in as pure a form as we can get for its exhibition; in the former we may have salts of potassa, tannic acid, and other ingredients, whose influence must not be overlooked.

After it had been shown that wine, given in hectic fever, would not increase the temperature, a number of writers, German, French, and English, found that, taken even by the healthy person, in doses of four or five ounces, it would reduce the temperature. So Ringer and Richards observed that the normal afternoon exacerbation of temperature would speedily go down after a few ounces of brandy. The experiments of Bouvier upon himself also conclusively showed that alcohol will lower the temperature in the normal condition. But experience at the bedside is yet more striking. For it is an important fact that all our febrifuges—as we have especially noted of quinine—will act much more decidedly in morbid than in healthy conditions. Similarly we have seen, in the experiments to which I referred at a former meeting, that while irritation of the crural, or other sensitive, nerve, in dogs, would at once diminish the temperature in health, this effect was more strongly marked in disease, as where fever had been excited by the injection of pus or septic matter into the veins. A good dose of alcohol will reduce the temperature by one, two, or three degrees, in a couple of hours, and sometimes in one hour or less. It is found that the reduction of temperature is in direct proportion to the amount of alcohol taken; and those of us who have been in the habit of using it much in practice know that even women and children, who have never touched it in health, will sometimes require immense doses—not ounces, but pints—of brandy in the diseases which demand its exhibition.

Now, if it be true—and it has been so proved—that alcohol will diminish the temperature the most notably in those persons who have not been accustomed to it in health, we should naturally look upon it as one of the principal febrifuges for women, and especially for children. Indeed, a monograph upon this very subject of the use of alcohol in the diseases of children has been put forth by a Frenchman, Dr. Godfrin. In what diseases, then, of children and others should alcohol be given? If it is an antiphlogistic, and will always reduce the temperature, why not give it in every febrile disease? To this I should be opposed. Alcohol should not be given in acute pneumonia, for example; for, when administered in large doses, only a part of the amount will be decomposed, and the remainder will be eliminated unchanged, not only by the kidneys, etc., but to a great extent also by the lungs. Now the lungs, which in acute pneumonia are the seat of congestion and nutritive disorder, would, in my opinion, suffer greatly from any new work put upon them. If the small amount of healthy lung is expected to get rid of this congestion, and to do the work of the whole lungs also, it should be spared the extra task of eliminating alcohol. Moreover, the *local* effect of alcohol is that of irritation. Whatever alcohol entered the lungs would act as a local irritant, and, despite the reduction of the general temperature, might increase the local congestion and inflammation. For this reason I would not give it in other acute inflammatory affections, unless the general condition of the patient required a stimulant in moderate doses. In enteritis, for instance, it would increase peristaltic action by its local irritation, and, therefore, would be contraindicated. But it is indicated in those fevers where we can get the general effect we desire without local injury, as in hectic fever, from whatever cause.

As a stimulant, I give alcohol for its antiparalytic effect. I may say that I regard it as a dietetic agent; and in the hot summer weather I make all my children take a little whiskey or brandy in the water they drink. For if there is anything to which we owe our great amount of intestinal catarrh, etc., it is paralysis of the nervous system from heat; and I find those children who take a little brandy to counteract this, every hot day through the summer, escape the bowel complaints, and do very much better. Like other physicians, I use alcohol in typhoid fever and secondary pneumonia; and most of the pneumonias we have to deal with in children are of this character, and very soon require the use of stimulants such as will at the same time reduce the temperature.

According to my experience, patients who are given alcohol as a febrifuge do not acquire a taste for stimulants. As soon as they begin to eat well they leave off the drinking of their own accord. I am asked how it is in cases of phthisis. In these, it is true, the patients will commonly drink until they die; but, as a rule, I do not make my phthisical patients take much alcohol, although there are some cases, attended by a good deal of fever, where it may do considerable good. I have wished to speak, however, only of those affections in which I have seen a positive indication for its use. In inflammatory fevers after the acute stage has passed by, and in chronic fevers throughout, whenever the

temperature gets very high or the pulse very frequent, alcohol is indicated.

I may once more state here that *camphor*, of which I have spoken at a former meeting, though formerly classed with alcohol as a simple stimulant, has like that the property of reducing the temperature. I have found, I believe, that the effect of alcohol is developed more speedily than that of camphor, but also passes off sooner. If I wished to get a very rapid stimulant effect, I should select, first, sesquicarbonate of ammonia; second, alcohol; third, camphor. Camphor in combination with quinine or alcohol does remarkably well in secondary pneumonia.

A word further also about *opium*, which was also the subject of some remarks some weeks ago. As an antiphlogistic it certainly has its own merits in a number of diseases, but chiefly those of adults. For children, I use it a great deal in enteritis and peritonitis; very seldom in other inflammatory diseases. Now and then, it is true, I employ it as an adjuvant—say, in pneumonia with very severe inflammation and intense irritation; but I have not seen sufficient reason to make it the principal remedy in any inflammatory condition of infants, save peritonitis. That I cannot recommend its wider employment may be due to lack of experience, perhaps because I have been so well satisfied with the other remedies.

LECTURES
ON,
THE PALSIES
AND
KINDRED DISORDERS OF THE NERVOUS SYSTEM.

By MEREDITH CLYMER, M.D.

Lecture VI.

PROGRESSIVE LABIO-GLOSSO-LARYNGEAL PALSY.

In continuing our study of the progressive palsies in their several modalities, we come to one but little known to the profession, and of which all our knowledge has been gained during the past decade; for ten years ago it was always confounded with ordinary facial paralysis, and is still so very generally. In 1841 the late Professor Trousseau saw a case of the kind in consultation, and he seized the main points of clinical significance, but, as he remarks, it remained a dead letter to him, and twenty years later it was recalled to his memory, and he was taught to recognize a new morbid species, by the paper of Dr. Duchenne (de Boulogne) on "Progressive Paralysis of the Tongue, Soft Palate, and Lips," published in the *Archives Générales de Médecine* (1861). And here let me remark how large a debt we owe this eminent and indefatigable observer; he has organized the clinical history of some of the most obscure, important, and interesting diseases of the nervous system, and where before there was either ignorance or uncertainty and confusion, there is now a well-ordered series of unquestioned facts. Since Dr. Duchenne first called attention to this form of palsy, many cases have been observed and carefully reported, along with exact histological examinations; its symptomology is complete, and we are getting definite notions of its morbid anatomy. The first didactic description of it in English I published in 1866. Duchenne now calls it progressive glosso-labio-laryngeal paralysis. It may be defined as:—

A form of local palsy, marked at the outset by incoördination of the muscles of the lips, tongue, and soft palate, with subsequent loss of motor power in these, and certain muscles of the larynx, and, frequently, in particular groups of those of the neck, chest, and arms; of slow development, and gradual and progressive course; the probable constant lesion being structural change in the associated nuclear origins of the motor nerves which are distributed to the implicated muscles, they undergoing pigmentary (yellow) degeneration, and atrophy.

This definition comprises, I believe, all the chief points that are positively known about this interesting affection. It is a palsy involving the lips, tongue, mouth, and larynx, interfering with the functions of eating, talking, and swallowing. The histologist and the physiologist have shown that the essential lesion should be one limited to a given and small physiological area of the medulla oblongata, and the morbid anatomist has proved, by very recent observations, that what ought to does happen; and that the special cell-nuclei, from which the facial, hypoglossal, laryngeal, and vagus nerves arise, and which are closely connected, become seriously damaged in structure, and that this is the starting-point of the morbid processus.

The invasion of true labio-glosso-pharyngeal palsy in its autonomous form is always gradual and insidious. The first symptom noticed is some indistinctness of speech, which if analyzed will be found to be due to the imperfect pronunciation of certain consonants, particularly the linguals and a little later the labials; this is occasioned by some disharmony in the muscular functions necessary to the proper articulation of words, and is soon followed by paresis of the orbicularis oris, certain muscles of the tongue, which is less nimble, and those of the soft palate. Deglutition at times seems difficult, and when eating the patient is liable to frequent spells of coughing, from small particles of food having "gone the wrong way." He notices, too, that saliva dribbles from the corners of his mouth, particularly when he is asleep, and on waking may find a spot on his pillow quite moist. Sometimes this is the earliest trouble. Food, too, may get into the posterior nares, or collect within the lips, or escape from the mouth, and occasion a good deal of annoyance. Mastication is fatiguing, and there is a tired feeling about the jaws after eating. Fluids are very apt to be awkwardly or slovenly drunk, dropping from the mouth after the glass or cup is taken away. Now this state of things may last for weeks or several months, and be looked upon by the patient, or even by the physician, if he should become alarmed and consult one, as a temporary inconvenience which will pass off. But very surely, after a variable period, these symptoms rapidly worsen, and the embarrassment of speech, mastication, and deglutition increases, until they are all very difficult, or almost impossible.

Let us examine the condition of a patient with this palsy in its stage of full development. His physiognomy is distinctive, and almost tells the tale of his trouble. There is a marked contrast between the upper and lower zones of the face; whilst the latter is motionless, the expression of the former is natural; he can wrinkle his forehead, knit his brows, wink and close his eyelids, and the movements of the eyes are perfect. Ask him to laugh, and you see at once that the lower part of the face is immovable, the upper half alone sharing in the act, or, as Trousseau says, "he laughs with his eyes." When the features are in repose you will remark a peculiar lachrymose and stupid look, and on examination will find that it is referable to the palsied orbicularis oris, which is the cause of the drooping lips, and the half-opened mouth, with the corners drawn somewhat upwards, the action of the zygomatic muscles being no longer opposed by the

labial sphincter. He is constantly slobbering, and always has his handkerchief in his hand to wipe his mouth and chin, and often coughs and spits to get rid of the saliva which accumulates in the mouth and throat. Bid him whistle and his attempts are ineffectual, he cannot purse up the lips, so that the necessary sound can be emitted; the same if you place a lighted candle before him and ask him to blow it out; he tries and tries again and fails, for he cannot direct the breath upon the flame; or should he succeed in extinguishing the light, you will observe a violent expiratory effort, as it is done not by the buccal but by the abdominal muscles. Here we have the proofs of the loss of motive power in the orbicularis oris. Examine the tongue; it can still be protruded, but to a much less extent than naturally, getting but a little way beyond the teeth; it has not its convex form, is hollowed along the middle line, and the edges are raised—in other words, it is guttered; the lateral movements are either lost or very imperfect, and the tip cannot be turned upwards. Here is another organ paralyzed in its motility, but its nutrition is good, for its size is not apparently lessened, the color is natural, and special and common sensibility are intact. If we look at the soft palate, we find it drooping, its tip lying sometimes upon the tongue, and very insensible to any irritant, shrinking slowly on its application. It is difficult to determine exactly the nature of the pharyngeal troubles. Inspection often shows no change in the position of the parts; both the anterior and posterior arches appear natural; but the nasal twang of the voice, and the constant return of fluids by the nose in the act of deglutition, show functional weakness in the muscular structure, which strangely enough is rarely susceptible of being otherwise satisfactorily demonstrated, as in the case of the lips and tongue. Whilst we are exploring the throat let us carry our examination a little further, and inquire into the condition of the larynx. The contractile power of the glottis is impaired, for if you cause the patient to take a deep inspiration, and then, when the lungs are fully dilated, to make any muscular effort, you will find that the air escapes so rapidly and violently through the larynx that the flame of a candle placed before the mouth will flicker or be blown out. This simple experiment is conclusive, and is confirmed by the laryngoscope, which shows that the glottis cannot be kept closed, for though the vocal cords may be brought in contact, it is only for an instant, for there is paresis of the thyro-arytenoidean muscles. Moreover, there is more or less falling of the epiglottis and more or less redness of the chink of the glottis, and the adjacent portions of the pharynx. Fauvel was the first, I believe, to indicate as a constant condition in this palsy the large accumulation of frothy saliva in the pharyngo-laryngeal infundibulum.

Let us now ascertain to what degree articulation is affected. It may be that there is actual mutism, a nasal sound only being uttered, and the intelligible pronunciation of a single word, or even letter, impossible. The extent of the malady, and the relative degree of motor weakness in the several implicated organs, are shown by the ability or inability to pronounce certain letters of the alphabet; those, for example, which need the action of the lips (*o, u, b, p, f, v, m*), or such as can be formed only with the aid of the tongue (*d, t, r, l*), or require a special direction of that organ (*s, z*).

The act of deglutition demands, as you know, 1. The preparation of the alimentary bolus by the teeth and saliva, and its collection into a mass by the tongue and buccal muscles; 2. Closure of the mouth during swallowing; and 3. The propulsion of the ball through the pharynx into the œsophagus, effected mainly by the tongue, and the muscles of the anterior arches, so that it must pass by the posterior orifice of the nose and the upper opening of the larynx without touching them. All these acts are imperfectly performed in this disorder, and finally not at all. The tongue, orbicularis oris, and buccinator being paralyzed, fail to dislodge or sweep up the food-ground to a soft pulp, and scattered over the mouth; consequently it collects about the teeth and in the pouches of the cheeks, and the patient endeavors to supplement the lost function by putting his hand over his mouth and on his cheeks, and thus force the passage of food into the pharynx. He is careful to masticate thoroughly, and this is a slow and sometimes difficult process, for the movement of diduction of the lower jaw is constantly weakened. On swallowing he throws his head back, and generally aids the act by drinking. In an advanced stage, morsels of food lodge in the larynx and threaten choking, and require violent efforts to free them. The appetite is good, but it is impossible to satisfy it on account of the small quantity of nourishment that can be taken; and the unfortunate sufferer, in addition to his other troubles, is tormented by constant hunger, and loses body-weight and strength. Coughing becomes impossible, and should catarrh intercur, the sputa is got rid of after terrible efforts, and suffocation seems at times imminent. In most cases there is no complaint of pain anywhere; in others it is felt, and that, too, at the outset, in the occipital and upper cervical regions.

As the disease slowly advances, respiration becomes embarrassed, and there is either continuous breathlessness, or it comes on in spells, particularly at night time; in the former case, along with other signs of defective oxygenation, there is sensible fall in the body-heat. The pulse is rapid, debility increases, the patient takes to his bed, and, propped up with pillows, lies with his head on one side, to let the saliva, which he cannot swallow, dribble from his mouth. In this condition some intercurrent lung disease may destroy life, a common ending, as we have seen, in these progressive palsies; or he slowly sinks from exhaustion, or inanition; or death may happen from the lodgement of food in the larynx, or by sudden arrest of the heart's action.

The most common complication is an extension of the paralysis to groups of muscles of the neck or chest, or of one or both upper extremities. Indeed I am disposed to believe that there are few cases in which sooner or later there is not involvement of most if not all of these muscles. Labio-glosso-laryngeal palsy may occur, too, in connection with progressive muscular atrophy or wasting palsy; cases have been reported by Duménil, Bazire, Charcot, Duchenne, and myself (1866), the initial phenomena being those of the latter disease, the morbid processus travelling upward. And since recent researches have proved the identity of the material lesion both in kind and histological site in the two affections, only occupying different physiological centres, their morbid connection can be readily understood. I shall have occasion in my lecture on wasting palsy to recur to this subject more in detail.

Dr. Duchenne, in his original memoir (1861), clearly indicates the probable *anatomical site of the lesion* in this disorder, reaching his conclusion from a study of the clinical facts without the satisfying proof of physical demonstration, for at that time he had seen no autopsies. He writes: Is not the lesion central? and is it not one and the same, interesting always in their origin, and without extending to the trunks or filaments, given nerves, namely; 1, the hypoglossal; 2, the motors of the soft palate; 3, those of the lips; 4, the spinal ac-

cessory, and, perhaps, the pneumogastric? In some subsequent post-mortem examinations made for Dr. Trousseau by Dr. Lhuys, both the latter and Dr. Duchenne became satisfied that the lesion was in the medulla oblongata, and were led to refer it to a sclerosis of that part of the cord. These examinations were made, however, before the minute anatomy of the medulla oblongata was perfected, and before the several forms of sclerosis of the cord were accurately studied. Indeed, until the exact anatomy of the medulla oblongata, and particularly of the parts found on the floor of the fourth ventricle, had been clearly established by the researches of Dr. Lockhart Clarke, and the internal connection of certain nerves engaged in the act of talking demonstrated, it was hard to positively establish the actual lesion and true pathogeny of labio-glosso-pharyngeal palsy. It is greatly to be regretted that this inestimable contribution, so admirably and convincingly illustrating the intricate relations of complex structures, clearing up many of the most obscure points of the anatomy and physiology of the nervous system, and consequently throwing much light on its pathology, should be in a form which makes it practically inaccessible to the great mass of the profession, and that it can be reached only through imperfect abstracts, or by personal courtesy, The dissections of Clarke show that the facial, vagus, hypoglossal, and laryngeal (internal branch of the spinal accessory) nerves arise from special nuclear cells situally contiguous, and that their rootlets have direct interchanging communications. Now this column of cells, the physiological centre of articulation, and intimately and necessarily connected with deglutition, is precisely the area "picked out" to borrow Dr. Wilks's phrase, to undergo the morbid changes which constitute the lesion of labio-glosso-laryngeal palsy. Anatomy, pathology, and experimental physiology beautifully lend their mutual aid in establishing this fact.

What are the properties of this lesion? I can only, at this time, briefly indicate them, as I shall have occasion hereafter, in the lectures on muscular atrophy and the essential palsy of infancy, to recur to and enlarge upon this interesting subject. I should, however, state at this time that it is to the labors of the Salpetrière School—to Dr. Charcot and his pupils—that we owe this important discovery of the real morbid processus in these disorders. What is the nature of the tissue-changes in these nuclear matrices, in these parent nerve-cells, of the *articulating and swallowing tract?* It may be told in a few words. It consists of *yellow pigmentary degeneration, with atrophy of the processes, nucleus, and nucleolus of the nerve cell.* The initial fact would seem to be the accumulation of pigment, the atrophy of the histological elements being secondary. Is the morbid processus active or passive? Is it or is it not preceded, or accompanied, by an irritative movement? This question we are not yet in a position to answer decidedly. There is reason to believe that the processus begins in the nerve-cell, that *it* is primarily attacked, and that the observed changes are not the results of exterior or communicated irritation, for the neuroglia or reticulum is unaltered; there are no traces of connective proliferation, or of fibrillary metamorphosis, nor any multiplication of myelocytes, nor areas of granular disintegration. Indeed, on comparing prepared sections of the same districts of the medulla oblongata affected with disseminated sclerosis, and those from subjects of this palsy, the different conditions of the connective tissue is evident. With our present lights we can, therefore, hardly admit the influence of an irritament acting first on the connective gangue, and thence propagated to the little nerve-centres. Through the kindness of Dr. Edward C. Seguin I have had an opportunity of examining the preparations of Dr. Charcot, illustrating the morbid histology of labio-glosso-laryngeal palsy, and of satisfying myself of the accuracy of his descriptions. I may add here that in those cases where the muscles of the neck, shoulder, and arm have been unilaterally affected, a similar condition of the nuclear origins of the nerves going to those parts has been found. But more of this at a subsequent time. The atrophied muscles are of a yellow color, and have undergone fatty degeneration. Though during life no change in the size of the tongue can be detected, the muscles after death are found altered and atrophied.

Duchenne's anatomical theory, broached ten years ago, founded on physiological induction, and now supported by indubitable histological facts, structural and pathological, admirably illustrates the mechanism of the series of clinical phenomena I have described. The initial trouble in sounding the labial and lingual letters, with the progressive embarrassment of articulation, until it is finally extinguished; the increasing difficulty of deglutition, with its attendant annoyances; the paresis of the muscles of the soft palate shown by the nasal voice; the lessened ability of diduction of the lower jaw; the weakened expiratory act, and the hurried action of the heart towards the terminal period, all are explainable by the damage which has been done, or is doing, to that federation of nerve-cells in nuclear communities which are echeloned along the floor of the fourth ventricle, and are, by means of multiple fibres, in connection with each other; and from which proceed the nerve-threads which carry from these centres the regulating current to the parts participating in the functions of talking, deglutition, and partly of respiration.

I can tell you nothing about the causes of this palsy, for nothing certain is known of them. So far all is conjectural, and I will not take up your time by talking of heredity or other unsupported hypotheses.

I will now briefly mention some of the affections with central injury of the nervous system that may be, and have been, confounded with labio-glosso-laryngeal palsy, and point out the *differential diagnosis.* In the first place, you may have paralysis of the vocal and articulating organs from damage to the special centres in the medulla oblongata other than that which I have described as the anatomical character of labio-glosso-laryngeal palsy. There may be hemorrhage about the origin of the nerves distributed to the tongue, lips, and pharynx, followed necessarily by about the same difficulties of speech and deglutition. Of such kind are the cases reported by Hérard, Proust, and Hughlings Jackson, and I believe that some of Dr. Wilks's, in the last volume of *Guy's Hospital Reports,* may be put in the same category. Or the mischief may be supra-bulbar, in the pons varolii, cerebral peduncles, corpora striata, as in Cornillon's case, where the autopsy showed disease of the corpus striatum and hemorrhage of the pons. But in these cases the onset is always sudden, and there is more or less hemiplegia; whereas in labio-glosso-laryngeal palsy the invasion is gradual, and the loss of articulation progressive. Such attacks are often recovered from, at least for a while, but there is always a risk of recurrence.

Double facial paralysis is very rare, and the hypoglossal nerve not being implicated, deglutition is not hindered, and the articulation of certain letters only, as *o, u,* is imperfect. All the muscles of the face are involved, the physiognomy is pathognomonic, the expression being blank and fixed, the patient seeming, as Duchenne says, to cry and laugh behind a mask.

In the general palsy of the insane—progressive general paresis—there is, at the beginning, the same

difficulty in uttering certain letters, especially the labials, as in labio-glosso-laryngeal palsy, and from the same cause, muscular incoördination; but the mental exaltation, the characteristic feeling of weariness in, and feebleness of, the lower limbs, the mask-like, doughy, facial expression, the constant twitching or tremulousness of the lips, and easy deglutition, &c., should make the differentiation of the two diseases facile, even to one not an expert.

Some cases of diphtheritic paralysis resemble more or less closely, at first sight, labio-glosso-laryngeal palsy; but here, besides the history of the case, you will find the force of the malady expended on the muscles of the pharynx, and, often, in a more or less degree, on those of the larynx, and that the chief difficulty is in swallowing, and sometimes in breathing.

I have seen a simulated type-case of this palsy in its developed stage in an hysterical girl—not the mutism so common in the temper-form of this dramatic disorder, but the rapidly progressive articulating and vocal troubles, and almost impossible deglutition; and very obstinate it was, and threatening too, from the difficulty we had in nourishing the patient.

I will not think that there can be any one so careless as to make a mistake in cases of the laryngeal neuroses, for even here the patient can nearly always speak in a whisper; or so uninformed, as to confound this palsy with aphasia, in which the legislative factor—the talk-centre—is at fault, whilst the executive factors, the muscles of the lips, tongue, palate, and larynx, are whole. There is no mechanical hindrance to speech, for the aphasic may be fluent with his meaningless gabble, whilst in the buccal paralytic capability of utterance is totally gone or is very small.

The progress of labio-glosso-laryngeal palsy is, as I have before said, often for a while slow, the articulation troubles and dribbling of saliva from the mouth, and some slight impediment of mastication and swallowing, being the only noticeable symptoms. In this state the patient may continue for months, or, exceptionally, for several years. So soon, however, as deglutition becomes sorely embarrassed, the expiratory act feeble, and the pulse very quick—sometimes the rate reaching to 150 and 200, owing to the cardiac complication—its course becomes rapid, and death happens in one of the ways already mentioned. It is doubtful if recovery has ever taken place in any case of the pure form of this palsy, that is, where it depended on the essential bulbar lesions; when cures have been asserted there were instances of its counterfeit presentment from, probably, bulbar or supra-bulbar hemorrhage. Dr. Trousseau says: "I do not believe that a single case of this disease is on record where its progress has been arrested even for a few months." Again, he says: "In the two first stages of the disorder the physician can perhaps not completely arrest its progress, but at least he can prevent it from being so rapid, and can relieve for a while; but his power does not go beyond this." I fear we are not yet able to gainsay this assertion of the lamented French professor. Now that we know the nature of the material change in the nervous centre, the prospect of successful interference hardly brightens. If we may hope for some success it can only be at the very outset, and then we do not see the case, or seeing it too often fail to recognize its character. Two cases of progressive disease of the cord in which I have been recently consulted, one of locomotor ataxy, and the other of disseminated sclerosis, had both been treated for sprained ankles and weakness in the legs, with no suspicion of their true nature. In this way precious time is lost, vital to the patient, and with the risk of prolonged misery, or even of life. The means I have before so often insisted on as the only rational method of treatment in this class of affections due to local nutritional errors, will give, I believe, if we have the opportunity of trying it in the early stage, the best chance for arrest if not cure. Later on all treatment must be hopeless. Relief, however, can be afforded by electricity, which temporarily restores, in a degree at least, the function of the palsied muscles, lessens the buccal and pharyngeal secretions, alleviates the difficulty of swallowing, and betters breathing by exciting the respiratory muscles.

Dr. Duchenne still insists on the efficacy of faradism, but the proofs of cure, or even arrest, by this means are wanting. The strongest evidence in its favor is Pellizari's case related by Tommasi; but here there was actually only improvement, and in this state the patient left the hospital, no further record being given, and the hope expressed that a permanent cure would result—the too common butt-end of such reports, which are so often mere springes set to catch the unwary, demoralized sufferer, and cheat him with impossible and unfulfilled promises. I believe that in the earlier stages the constant current is better suited to these cases than the induced, which I think I have seen do harm; whilst later, when the paralysis is declared, local faradic electrization gives much help and comfort.

CLINICAL LECTURE ON LITHOTRIPSY.

By J. W. S. GOULEY, M.D.,

PROFESSOR OF CLINICAL SURGERY AND GENITO-URINARY DISEASES IN THE UNIVERSITY OF NEW YORK, SURGEON TO BELLEVUE HOSPITAL, ETC.

GENTLEMEN—The patient who is now before you, suffering from stone in the bladder, has already been subjected to six sittings at *lithotripsy*, and will afford me the opportunity to give you some practical hints in regard to the *modern* method of performing the operation.

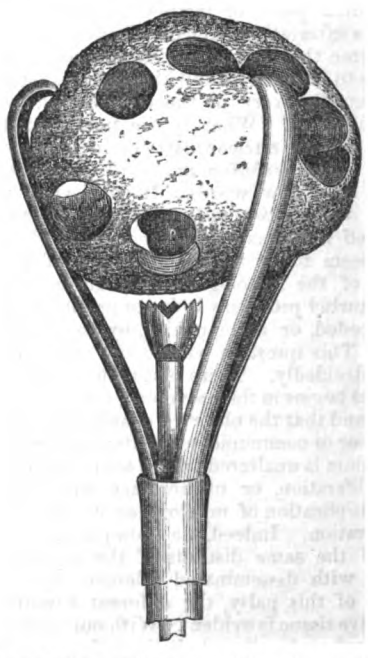

FIG. 1.—The vesical extremity of the trilabe and perforator, such as Civiale used in his early operations, showing a perforated calculus within the grasp of the instrument.

For the removal of this troublesome ailment, cutting operations had been almost exclusively resorted to until 1824, when Civiale demonstrated, by several successful operations, that vesical calculi could be reduced to powder or broken up into fragments small enough to be expelled with the urine; all this was accomplished without a stroke of the knife. At the time M. Civiale made his discovery he was not cognizant of the efforts—in the same direction—of the Bavarian surgeon Gruithuisen, nor was the latter aware that the ancients had sometimes resorted to successive perforations and to crushing for the destruction of stone in the bladder.

Fig. 2. First model of Weiss' lithotriptor.

The method by successive perforations with straight instruments continued to be employed on the Continent by Civiale, Leroy d'Etiolles, Heurteloup and others, until 1831, when Dr. Jacobsen of Copenhagen devised a curved instrument known as the brise-pierre-articulé; but this was not the first curved lithotriptor, for Mr. Elderton had produced one as early as 1819, and in 1824 Mr. Weiss, surgical cutler of London, constructed a curved stone-breaker (Fig. 2) which was first used by Sir Benjamin Brodie, who afterwards greatly improved it.

After having seen the last-named instrument, Baron Heurteloup conceived the idea of his "percuteur courbé à marteau," which he described in the "Mémoires sur la lithotripsie par percussion" presented to the French Academy in 1833. He found the curved percussor of easier introduction, and better adapted to seize and pulverize the calculus, than were the straight instruments, and he called the operation *lithotripsy*, which conveys the idea of *pulverization*, while *lithotrity* means *perforation* of the stone. Our *modern improved lithotriptors* are all modelled after Heurteloup's curved percussor, but the shape of the blades has been so altered as to guard against injury to the mucous membrane of the bladder; besides, pressure by means of the screw, and the rack and pinion, has been substituted for percussion. Their superior, and at the same time simple construction renders the operation very much easier, safer, and more rapid than it was formerly.

Lithotrity was successfully performed in this city in the latter part of 1830, by Dr. Depeyre, who used the trilabe and perforator of Civiale.* He was followed by Dr. J. Randolph of Philadelphia, who made his first trial in September, 1832, with the trilabe also, completing the operation with Jacobsen's brise-pierre-articulé. (Figs. 3 and 4.)

Dr. Randolph has given accounts of nineteen cases of stone in the bladder, with one death; in nearly all of them he employed the brise-pierre-articulé with great satisfaction and no untoward accidents.†

Dr. Gibson of Philadelphia gave his preference to Heurteloup's instrument.

Among other surgeons who have frequently resorted to the operation in this country, are Drs. N. R. Smith of Baltimore, Pancoast of Philadelphia, Buck, Post, Van Buren, and Wood of New York.

These few facts bearing upon the history and progress of lithotripsy will suffice for our present purpose, and will not occupy your time with details which you can learn from books. If you wish to become erudite, let me refer you to the early works of Leroy d'Etiolles, Civiale, Amussat, Heurteloup, and Ségalas, which contain all that is worth knowing about the early history of the subject.

Fig. 3.—Jacobsen's instrument closed for introduction.

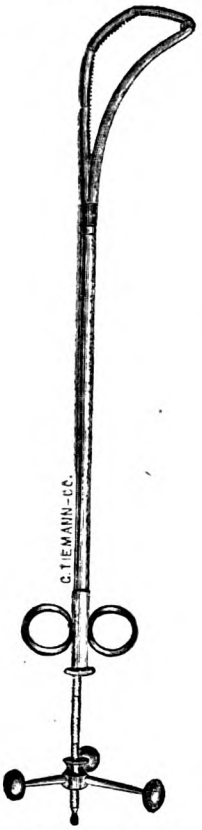

Fig. 4.—Jacobsen's instrument opened for seizure of the stone.

The treatment preparatory to lithotripsy is of the utmost importance, and upon it will frequently depend the ultimate result of the operation. When a calculous patient presents himself to you, do not at first attempt to sound, but allow him a few days' rest in the horizontal posture, with a pillow under the hips, in order that the stone may roll back to the less sensitive part of the bladder. Ascertain whether he has acquired the habit of using opiates to relieve pain; if so, diminish the dose gradually until he is able to abstain from the drug; meanwhile let his bowels be properly regulated. Diluents, tonics, and a nutritious diet will together make an excellent substitute for the narcotics, and will do more than anything else to tranquillize his nervous system and improve his general health. He should be directed to micturate only while lying down, that the calculus may not be forced against the vesical neck; it may be difficult at first, but in a few days he will experience no trouble in emptying his bladder by turning to one side or the other, or even when upon his back. Do not permit him to get up until this is accomplished, and the urine can be retained for one and a half or two hours. The first exploration should be made with soft bulbous bougies, to estimate the calibre of the urethra and ascertain its degree of sensitiveness. If the meatus urinarius is too narrow to admit

* See *New York Medical Journal*, February, 1831, p. 388.
† *American Journ. Med. Sciences*, Nov. 1834, Nov. 1836, Nov. 1837, and *Medical Examiner*, Vol. I., 1838.

a fair-sized lithotriptor, it should be freely incised. The bladder is then explored with a searcher,—Thompson's is, I think, the best,—that an approximate idea may be formed of the size, number, and character of the calculus or calculi. If the general health of the patient is good, and his urinary organs are in a fair condition—if, in a word, there is nothing to contra-indicate the operation of lithotripsy, the next step in the preparation of the patient is to introduce into the bladder, on alternate days, steel sounds of increasing size, so as to distend the urethra even up to No. 15 or 16 of the English catheter scale. This accustoms the parts to the contact of instruments, and the patient, at first timorous and sensitive, is soon anxious for the first crushing. Afterwards a lithotriptor should be introduced, the stone seized and measured, and, while it is in the grasp of the instrument, rotation to the right and left and a back and forth movement should be made, in order to ascertain the presence of other calculi. This procedure may be repeated in four or five days. Having thus become familiar with the case and obtained the patient's full confidence, give him a day's notice for the first sitting; let him take an enema on the morning of the operation, and lie abed with a pillow under the hips at least an hour before the time appointed. The duration of the preparatory treatment should depend upon the state of the patient's general health, the degree of tolerance of his bladder and urethra, and the size and quality of the stone. In a simple case, one week's preparation will suffice, while in others from four to six weeks may be required.

I exhibited to you on a former occasion nearly all the different instruments which are obsolete, without giving you any detailed description of them, nor will I attempt to do so to-day, for my object is to teach you the *modern* method, and I shall endeavor to abstain from any remarks which are not essentially practical. As I shall frequently appeal to your sense of sight, my description of the instruments now in use will be brief. Bear in mind that the first thing to be accomplished in lithotripsy is the reduction of the stone to fragments, and the next is the pulverization of these fragments, that the detritus may be expelled without creating much irritation in the urethral mucous membrane.

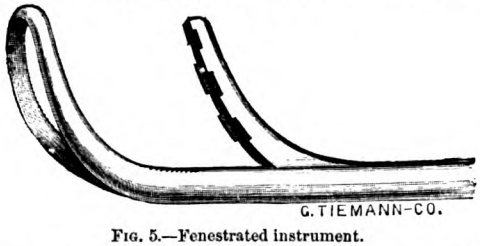

FIG. 5.—Fenestrated instrument.

The modern lithotriptor consists of two blades (Fig. 5), the shaft, the sliding-rod, and the handle. The two blades together when open are sometimes called the jaws, and when closed, the beak. The blade that is immovable and fixed to the shaft is called the *female*, and receives the *male* blade, which is continuous with the sliding-rod, and is susceptible of a back and forth movement. I now indicate to you the average curve of the beak (Figs. 5 and 6): the less the angle the greater the power, and, vice versâ, the greater the angle the easier the introduction. The beak ranges from No. 10 to No. 15, for adults.—For fragmentation of the stone, the better and safer instrument is the fenestrated lithotriptor (Fig. 5), because of its great power and strength. For pulverization, use the instrument with plain blades (Fig. 6); the male should be narrower than the female blade, to enable the operator to force out the impacted detritus. But the operation can be completed with the fenestrated lithotriptor, and it can also be begun and terminated by means of a strong instrument with plain blades. The scoop lithotriptor is no longer in use, and has been

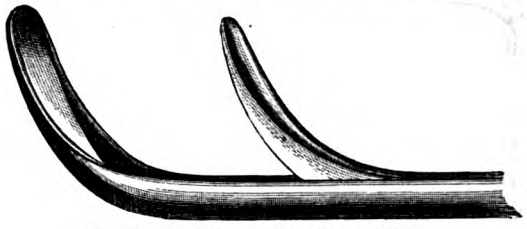

FIG. 6.—Lithotriptor with narrow male blade.

replaced by the plain-bladed instrument just mentioned, and which Civiale calls his "lithoclast."—The shaft should be at least ten inches in length, and not less than two numbers smaller than the beak. The motive-power resides in the handle of the instrument. M. Charrière of Paris deserves much credit for having made a very simple but important alteration in the mechanism of the screw lithotriptor by his adaptation of the *écrou-brisé*, which is a nut consisting of two segments that can be approximated or separated instantly by turning the movable disc in the handle; in this manner the screw-power can be applied or detached at will, so that the male blade and sliding-rod can be fixed, or can be withdrawn to the required extent without unscrewing. (Fig. 7.) This is a very valuable improvement, inasmuch as economy of time is of the greatest moment in the operation.

FIG. 7.—Handle of Charrière's instrument.

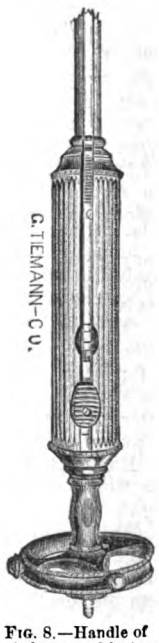

FIG. 8.—Handle of Weiss's improved instrument.

The same motive-power is adapted to the English instrument, with the substitution of a sliding button (Fig. 8) for the disc: you observe that here the handle is cylindrical, and much more convenient for manipulation than the French. Both of the instruments I now show are of equal weight (7½ oz.), although the English looks larger and heavier.

The patient should be placed in the horizontal position, upon a firm bed or a table such as you see, and

his pelvis should be elevated by means of a hard hair or straw pillow placed beneath. Formerly the bladder was injected with six or eight ounces of warm water, but now this is entirely done away with; the urine is simply allowed to accumulate to five or six ounces, and no instrument, save the crusher, is introduced. If the patient has been carefully prepared for the operation, no difficulty will be experienced in the introduction of the lithotriptor. I would like you, however, to remember always that the curve of the instrument differs materially from an ordinary catheter, and that the same rule for introduction will not apply to both. To pass the lithotriptor into the bladder successfully and without doing damage to the parts, you have but to adopt the directions given by all modern lithotriptists; they are briefly as follows:—

Stand upon the right of the patient, with your back half turned towards the head of the bed or table, and having warmed and oiled the instrument, seize the penis laterally behind the corona with the left thumb and index, and keep it in the vertical position; then, holding the lithotriptor horizontally with the right hand, so that its long axis is at a right angle with the patient's body, introduce it gently and slowly, altering the position by a gradual sweep until it is brought to the perpendicular, and has reached the bulbo-membranous junction of the urethra. Keep it in this position for a moment, when you will feel it sliding into the membranous portion; then depress the handle between the thighs until the instrument has passed the prostatic portion, and it will enter the bladder, and come in contact with the stone by being pushed onward. Should you endeavor to introduce it as you would a catheter, the upper wall of the urethra in front of the triangular ligament would surely be torn across; an accident which might prove very serious. The introduction of the lithotriptor is perhaps the nicest and most important step of the operation; unless it is properly performed, you need expect but the most untoward results.

The next point is to find the stone and get it between the jaws of the instrument. Remember that the field of operation is very small, that the instrument must be kept in the median line, and that it should interfere with the coats of the bladder as little as possible, or, to use Thompson's words, "the operator should exert the largest amount of influence on the stone with the smallest amount of disturbance to the bladder." There are two modes employed to seize the stone. In one, Sir Benjamin Brodie's, the blades are depressed on the basfond and posterior wall of the bladder so as to make them the depending portion, where the stone is likely to roll; then the male blade is withdrawn, and in the majority of instances the calculus will fall between the jaws of the instrument. If the stone is not caught, a gentle stroke may be given with the fingers to the handle of the lithotriptor, and, as Brodie says, "the slight concussion thus communicated to the bladder will be sufficient to dislodge the calculus and bring it within the grasp of the instrument." Here the object is to bring the stone to the instrument, while in the other (Civiale's method) the instrument is applied to the stone, and as little movement as possible is made. As the lithotriptor enters the bladder, the beak is slightly turned to one side, and then to the other, to ascertain the position of the calculus. The moment it is felt, the instrument is turned toward the side opposite the stone and pushed onward into the bladder, the male blade is cautiously withdrawn, then the open instrument is turned over on the side of the stone, is closed, and the foreign body seized. —To Sir Henry Thompson, who, after Civiale, has had the largest experience in lithotripsy, and has done so much for its advancement, belongs the credit of having greatly perfected and simplified most of the details of the operation, and I am only repeating what he teaches. He describes five positions to be given to the vesical extremity of the lithotriptor in order to find and seize calculi or fragments; they are the "vertical, right and left incline, right and left horizontal," and they enable the surgeon to explore the bladder in the "middle, right, and left."—The calculus, once caught, is fixed between the jaws of the lithotriptor by one or two slow turns of the wheel; then it may be turned more rapidly, until the stone is fractured, when the screw-power is detached, the male blade withdrawn, and fragment after fragment is caught and crushed, perhaps to the extent of four or five; but the sitting should not exceed five minutes—make it three, if possible.

After this, the first sitting, a hot fomentation is applied to the hypogastrium; the patient is kept in the horizontal posture for twenty-four hours, is directed to micturate only while in that position; and all the urine he passes is strained, and the detritus preserved. For the first twenty-four hours scarcely any fragments will be expelled, and it is all the better, for their angularities are soon smoothed by mutual attrition in the bladder, and those which remain longer become water-worn, and cause little or no irritation in their outward passage. Small calculi are often destroyed at one sitting, but larger ones require five, six, and sometimes many more. If the first sitting has not been followed by any accidents, and the stone is neither too large nor too hard, allow four or five days to elapse before the second sitting, when you should use the lithotriptor with a narrow male and flat female blade. (Fig. 6.)

If you can always reduce a stone to powder, you will not require more instruments than those already mentioned; otherwise, you will sometimes have need of the urethral lithotriptor and the long slender forceps for the extraction of fragments impacted in the urethra. If the bladder and urethra are in a fair condition, you will seldom have occasion to use injections and evacuating catheters, for you may confidently expect the complete and spontaneous expulsion of the detritus. In pulverizing fragments, a certain amount of débris will almost always be impacted between the blades, and unless the instrument is properly constructed, you will not be able to get rid of it, and, in withdrawing the lithotriptor with its jaws only partially closed, the neck of the bladder and urethra may suffer. It is only with the improved lithotriptor that the detritus can be properly expelled from the beak; here the male blade is not only narrower than its fellow, but it is slightly bevelled from the centre to the edges on the crushing surface, and acts upon the mud-like detritus after the manner of a wedge, and instead of scattered teeth-like projections to prevent the stone or fragments from slipping away, as in the ordinary instrument, it has oblique serrations, which also serve as gutters for the better expulsion of the soft débris. The manipulation necessary to drive away detritus impacted between the blades is described in a few words by Civiale. He says the surgeon grasps the handle of the instrument with the left hand, while with the right he executes upon the wheel slight movements of semi-rotation that approximate and separate alternately the jaws, which act upon the accumulated calculous matter so as to drive it out by the interval between the blades when closed.

Before I proceed to illustrate the principles of modern lithotripsy by crushing some of the fragments which remain in the bladder of our patient, let me give

you the result of the case which some of you saw here in June last.

The patient, a man aged twenty-four, had been afflicted with calculous disease for fourteen years; otherwise healthy. Latterly his symptoms had become so urgent that he was compelled to seek surgical aid; he resorted to this hospital for treatment, and was kindly transferred to me by my colleague, Dr. Sayre, in whose service he had been. He was then suffering greatly from vesical tenesmus and very frequent micturition; but after a few days' rest in the recumbent posture, he improved sufficiently to undergo a critical examination. There was nothing found to contra-indicate the operation of lithotripsy, and he was prepared; in three weeks he was in excellent condition for the first crushing, and within two months from the date of his entry he was dismissed, cured. During the whole course of the treatment he had scarcely an untoward symptom. Only one of the seven sittings which he underwent was fruitless; and he passed altogether two drachms of detritus which I now show you. Observe that there are no fragments which could not have passed easily through the urethra of a boy twelve years old, and that the larger proportion of the detritus is powdered. The calculus is phosphatic, with a small uric acid nucleus which you will find among the fragments. This case was attended with no complication, and progressed to a speedy and happy termination. Both the fenestrated and plain-bladed lithotriptors—Weiss's last model—were used, and there was no trouble in finding and pulverizing the last fragments.

Our patient of to-day arrived in the city on the 13th of July, consigned by Dr. Wm. Cunningham, of Clarke Co., Ky., to my excellent friend and preceptor, Dr. Van Buren, who asked me to take charge of him. He is 27 years of age, of good constitution, and has had symptoms of stone for nine years.

The preparatory treatment in this case lasted one month, on account of cystitis. Two calculi were discovered; one measuring 1¼ by 1¼ inches, the other 1 by 1¼ inches or thereabouts. The first crushing was effected August 13th, with the fenestrated lithotriptor, and the smaller stone broken up; by August 17th he had passed 29 grains of detritus, with some angular fragments, but no urethral inflammation had supervened. The second sitting was productive of but 8 grains. At the third sitting the other calculus was seized and crushed, much more force having been required to break it. Fourth sitting, Civiale's lithoclast was used, and five grains were brought out. At the fifth sitting, the fenestrated instrument was used once more, and this because there remained one or two large fragments of the harder concretion which required the more powerful lithotriptor. Sixth sitting:—The improved English plain-bladed instrument was employed, several fragments powdered, and the impacted detritus readily expelled from the beak. The detritus thus far collected amounts to 144 grains. and is contained in the vial which is here for your inspection. Compare it with the other, and you will notice that there are more angular fragments, made as you know by the fenestrated instrument, and that the proportion of powder is less.

Now the patient is in proper position; observe that his pelvis is elevated about 2½ inches, his heels close together, his knees separated, and his legs and thighs a little flexed. At this, the seventh sitting, the improved English lithotriptor with plain blades will be used. Watch the manner of introduction. Now I stand upon the patient's right, and, seizing the penis as before described, I pass the instrument into the urethra;—it is progressing with apparent slowness—it has already reached the bulbo-membranous junction and assumed the vertical direction. Now that I feel it entering the membranous portion, I begin to depress the handle between the thighs—the beak has reached the bladder and is in contact with a fragment. The blades are opened, turned to the left, and the fragment, ¼th of an inch in size, is caught; now I crush it. Opening the instrument again, I seize another small fragment and powder it—a third fragment is crushed; and now, by a few quick short turns of the wheel to the right and to the left, the detritus is nearly all expelled: the blades are closed, and the instrument is withdrawn. The lithotriptor was very little over one minute in the bladder. I have made this a short sitting, because the passage of angular fragments had previously caused a little irritation; the other sittings have varied from two to five minutes. The patient will walk down to his ward and remain quiet until to-morrow, when he may get up if he feels so disposed.

The next patient to be placed upon the table is a complicated case—65 years of age—has an enlarged prostate and a perineal fistula, which followed lithotomy performed last spring. It appears that the stone was broken during extraction, and in a few months, symptoms of calculus recurring, he was lithotriptized (in July last); but all the fragments were not extracted. Still suffering from his old symptoms, he was sent to the hospital, and came under my care. Time will scarcely permit me to give you all the details of this case, but I hope soon to do so. Here is a little detritus which I have taken from his bladder at previous sittings by means of Civiale's lithoclast and the evacuating catheter. The pelvis of this patient, as you see, is more elevated than was the last, for obvious reasons. The instrument will not be kept in his bladder more than a minute, if possible. You see there is no difficulty in introduction. The blades are opened, turned to the right and left, then reversed, but nothing is seized; nor can any fragments be caught by the method of Brodie: possibly there are no more, but in the course of four or five days another attempt will be made. The instrument is withdrawn, and you see there is nothing between the blades.

There are other points in the modern operation which I shall not have time to give you to-day, but I shall take an early opportunity to dwell upon them, and to give you the statistics of the French, English, and American lithotriptists. I cannot conclude, however, without exhorting you to pay the strictest attention to the details of the operation; for, as says the eminent English surgeon, lithotripsy negligently performed is worse than if not done at all.

Original Communications.

A CASE OF ŒDEMA GLOTTIDIS

IN WHICH

A PATIENT WAS RESUSCITATED BY THE OPERATION OF TRACHEOTOMY AFTER RESPIRATION HAD CEASED.

REPORTED BY GURDON BUCK, M.D.,

SURGEON TO THE NEW YORK HOSPITAL, FELLOW OF THE NEW YORK ACADEMY OF MEDICINE.

On Sunday evening, Nov. 23d, 1851, about 10 o'clock, at the request of Dr. M. Morris, my former pupil, I visited John Vance, an Irish laborer, 23 years of age, at the house of his employer, Mr. Gallagher, on the corner of Fifth avenue and 57th street. We found the patient sitting up in bed and suffering from extreme dyspnœa; his breathing was hurried and labored. In-

spiration required great effort, while expiration was comparatively easy; his face was livid, his lips purple, his eyes prominent and suffused, his countenance extremely anxious. His whole body was drenched in perspiration; his pulse was 98, full, strong, and bounding. His intellect remained clear and undisturbed; he appeared to understand perfectly every question put to him, and though he made the utmost effort to reply, he was unable to articulate a single syllable, the voice being entirely extinct. Deglutition was almost impossible.

On the Saturday evening previous, without preceding indisposition, the patient first perceived soreness of his throat, which increased the following morning. He was also otherwise indisposed, and took no food at breakfast. During the forenoon of Sunday he imprudently exposed himself with his throat uncovered, and at 12 o'clock was first sensible of difficulty in breathing. At 4 o'clock P.M. other members of the family remarked that his voice was very much changed; about the same hour he ate with tolerable facility a bowl of stirabout and milk. Towards evening his symptoms increased in violence. Dr. Morris saw the patient first at 9 o'clock, and found him in a state of desperation, tearing his hair, grasping at everything within his reach, and frantic to obtain relief from impending suffocation. He found the epiglottis swollen nearly to the size of the end of his thumb, pulpy and folded upon itself, so that its edges touched each other at the summit. The velum and uvula as well as the fauces were much swollen. The doctor at once resorted to free scarifications of the velum and uvula, which he made with a sharp-pointed bistoury. They bled freely and afforded marked relief.

Not willing, however, to rely on these means alone in such imminent danger, Dr. Morris lost no time in obtaining assistance. Happily for the patient, as the sequel will show, I provided myself on leaving home with a trachea tube and scarifying-knife for the larynx. When we reached the bedside of the patient, Dr. M. remarked, that though the patient was more tranquil, his symptoms were more alarming than at his first visit. The bleeding from the scarifications already made continued remarkably free, so that at short intervals the patient spit blood by the mouthful. The danger of suffocation was imminent, and no time was to be lost in endeavoring to afford relief.

The patient was assisted to sit upon a chair, his head, thrown a little back, was supported by one of his companions, and a cork held between the molar teeth of the left side. Placing myself in front of the patient, I passed my left forefinger in at the right angle of the mouth, over the tongue, till it reached the epiglottis, which was found swollen, pulpy, and folded upon itself as already described, overlapping the epiglottis. I pressed it forward towards the base of the tongue, and then conducted the scarifying-knife along the back of my finger till it arrived at the nail, when I elevated the handle of the knife and consequently depressed its blade, so that its cutting edges descended into the larynx between the swollen aryteno-epiglottic folds which bound its entrance on either side. To scarify these swollen œdematous walls, a slight semi-rotary movement was given to the knife, first to one side, then to the other, in the act of withdrawing it.

The effect of this operation was watched with anxious solicitude. The blood continued to flow freely from the previous scarifications, but no relief of the urgent symptoms was perceptible. I now remarked to Dr. M., I was afraid it would be necessary to resort to tracheotomy. After waiting a few moments longer I repeated the scarifications in the same manner. On withdrawing my finger with the knife, I at once noticed that the blood no longer flowed from the patient's mouth as before, and that his breathing was suspended, though without any spasm or struggle. His countenance was changing, and losing all power to remain in an erect position, he sank down from his chair upon the floor in a state of complete relaxation and insensibility. His features were assuming a death-like expression, and respiration was recurring only at longer intervals and with rapidly diminishing force. In a word, the patient was literally dying.

Kneeling over him, as he lay stretched upon the floor, I proceeded with the least possible delay to open the trachea and insert the tube I had brought with me. Dr. Morris with one hand held a dim lamp, and with the other supported the head, to prevent it rolling to one side. My left forefinger, being placed upon the crico-thyroid space, served to keep the parts steady and to determine the starting-point of my incision, which was carried as exactly as possible along the median line, two inches downwards, over the trachea. After cutting through the skin, the division of the deeper tissues was guided entirely by the touch, without regard to hemorrhage, my aim being to arrive at the three or four upper rings of the trachea. As soon as these could be distinctly felt by the finger, the knife (which was a straight French bistoury) was plunged perpendicularly into the trachea. Its entrance was accompanied with a slight hissing noise. In endeavoring to enlarge the opening downwards with a blunt curved bistoury, some delay and embarrassment arose from the edges of the wound overlapping the opening in the trachea and preventing the entrance of the knife; the enlargement, however, was effected, and the tube at length introduced. Instantly blood welled up through the tube, from the trachea, which doubtless had flowed into it from the fauces as well as from the external wound. I immediately applied my mouth over the tube and sucked up the blood from the trachea, repeating the process several times in quick succession; I also breathed into the trachea to inflate the lungs. Soon, to my unspeakable satisfaction, an effort was made to expand the chest, followed by a bubbling of air through the tube; this was succeeded by renewed efforts, at intervals gradually diminishing in length, till respiration finally became re-established, but not without fears that the success of the operation might be prevented by the profuse hemorrhage from the wound, which constantly flowed into the trachea. However, by pinching together the edges of the wound around the tube, and promptly wiping away the blood as fast as it was expelled from the trachea at each expiration, and also occasionally repeating the suction, this formidable difficulty was at length surmounted, the hemorrhage gradually ceased, and the trachea freed itself from obstruction.

The patient's countenance slowly resumed a natural expression and the lips lost their livid purple hue. His pulse, which, till now, it had been impossible for either of us to examine, had become steady, though considerably reduced in force. Consciousness soon returned, and within half an hour we left our patient in a most comfortable condition, breathing with perfect tranquillity through the tube, and with the prospect of enjoying a quiet night.

On Monday morning, at 10 o'clock, twelve hours after the operation, we found our patient had passed a comfortable night, though he had slept but little, from fear of trusting himself to sleep. Respiration was performed through the tube without the slightest effort; the secretion from the trachea was slightly discolored with blood. A fresh tube, with a large opening at the bend on the convex side, was substituted for the one

he had worn since the operation. On closing the outer orifice of the tube the patient was able to breathe through the larynx with a moderate effort, and also to speak in a distinct whisper, showing conclusively that the obstruction in the larynx, from œdema, had already diminished to a considerable degree. The epiglottis was felt to be less swollen and less folded upon itself. Deglutition was also less difficult; pulse moderately accelerated, without fever. Ordered to take one ounce castor oil, and restrict himself to gruel for nourishment. The tube to be changed at evening.

Tuesday, the 25th, at 10 o'clock A.M., found the patient progressing very favorably. He had slept well, his bowels had been freely evacuated, and the tracheal secretion had lost its bloody tinge. After inserting the perforated tube as before and closing the outer orifice, it was found that the obstruction of the larynx had still further diminished, respiration was performed with less effort than the day previous, and the patient now spoke in a clear, full tone. Deglutition had further improved; the swelling of the epiglottis remained about the same. The pulse was 96, and of good strength. Cough seldom occurred. Patient was allowed his favorite dish of stirabout and milk.

Wednesday morning, the 26th, patient continued doing well in every respect. Respiration through the larynx scarcely required any effort. Preparatory to the entire removal of the tracheal tube a cork was left in its outer orifice and the patient instructed to remove it himself if necessary.

Thursday, 27th, at noon, about-eighty two hours after the operation, the tube was left out entirely, and the wound of the neck allowed to close up. The swelling of the epiglottis diminished very slowly; its existence, however, did not apparently embarrass either deglutition or respiration.

The rapid subsidence of the œdematous swelling of the glottis, permitting, as it did, the trachea tube to be dispensed with on the fourth day, is worthy of special notice. It was unquestionably owing to the scarifications that immediately preceded the opening of the trachea, no other treatment having been resorted to. This conclusion is corroborated by comparison with other cases where tracheotomy alone has been successfully employed in treating this disease, and in which the tube had to be worn for two or three weeks. On the tenth day after the operation (Wednesday, December 3d) the patient was exhibited at a meeting of the Academy of Medicine in the small chapel of the University. The wound of the neck had nearly healed, and air no longer escaped through it.

Convolvulin and Jalapin as Purgatives.—Drs. Köhler and Zwicke published an essay in *Neues Jahrb. f. Pharmacie* on this subject, the following being their conclusions:—

1. That the purgative action of these substances depends on the presence of bile in the bowels, with which they may mix and be dissolved. Whilst 0·3 grm. caused death when administered to a guinea-pig, by producing enteritis, as much as 1 to 2 grms. could be given without effect when the ductus choledochus had previously been tied.

2. The drastic effect is due wholly to local irritation of the mucous membrane. They injected subcutaneously and into a vein as much as 0·5 to 1·5 grm. without any effect.

Perineuritis.—This is the name given by Galezowski to inflammation which seems chiefly to affect the outer neurilemma.

Sarcinæ.—*Sarcinæ* and yeast fungi are occasionally found by means of the microscope in the vomit. These organisms are the result of a process of fermentation. Of sarcinæ we knew nothing previous to their description by John Goodsir, in 1842.

New Theory of Nervous Action.—At the last meeting of the Royal Irish Academy, Dr. R. McDonnell, F.R.S., read a paper on "A New Theory of Nervous Action, as regards the Propagation of Sensation along the Nerves."

The author's paper might be briefly described as an application of a theory, similar to the wave theory of light, to the propagation of sensations along the nerves.

He confined this "undulatory" theory of nervous conduction with the hitherto more generally received hypothesis of distinct nerve conductors, supposed to exist for each kind of sensation (pain, heat, tickling, &c.), and attempted to point out that the former is at once a simpler hypothesis, and more in harmony with the ideas now prevalent as to the propagation of light, heat, electricity, &c.

The author also dwelt upon many points of analogy between the absorption or interception of waves of heat or of light, and the somewhat similar phenomena as regards nerve conduction where one kind of sensation is felt, and another ceases to be any longer perceived, as in cases where the patient feels the contact of the hand, but cannot distinguish heat, or *vice versâ*.—*Med. Press & Circular.*

Carbolic Acid Internally in Syphilis.—In the *Arch. f. Dirmat. und Syph.*, Dr. M. Kohn reports the results obtained by Professor Hebra. The acid was generally given in pill, and was used only in the exanthematous forms of the disease with any apparent success. These, however, improved or disappeared under the use of the remedy in four to seven weeks. Hebra cannot recommend this agent, since mercurials act much more quickly; and the carbolic acid is quite ineffectual against the nocturnal pains and affections of bones and joints.

Therapeutics of Spinal Diseases.—Dr. Heaton, of Leeds, after giving the details of a case of paraplegia recently treated by him, says:—"The therapeutics of spinal diseases seem to be very much in the shade. On the theory of causing absorption of effused matter into and around the cord, iodide of potassium was given. To lessen the blood-supply to the congested structure, belladonna; aperients for torpid bowels, and electricity to maintain and promote the enfeebled muscular contractility. The benefit from any and all of these means was very small." We quite coincide in the gloomy view taken by Dr. Heaton as to the present state of therapeutics in spinal disease.—*Med. Press & Circular.*

Disease of the Stomach.—Dr. Wilks says that in cases of persistent vomiting, accompanied by hematemesis, it is necessary to ascertain whether the food comes up immediately, or after it has passed into and remained some time in the stomach. In the former case, there may be some contraction of the œsophagus; in the latter there is a probability of the stomach being diseased either with cancer or ulcerated. In cases of gastric ulcer, hematemesis may be slight or severe; when arising from disease of the liver, it is always excessive. He looks with disfavor on the plan of passing bougies for the treatment of œsophageal diseases from morbid deposit, since the contraction of the tube from this cause is not at all analogous to that of stricture of the urethra.—*Med. Press & Circular.*

THE MEDICAL RECORD.

A Semi-Monthly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

New York, October 1, 1870.

AMERICAN MEDICAL JOURNALISM.

THE general want of success of Medical Journalism in this country is, we are compelled to say, a fact. The profession has no cause to complain that it has not had periodicals enough, but that they have had, comparatively speaking, such a short existence. Of one hundred and twenty medical journals that have made their appearance within the last fifty years, fully one-half were discontinued within from six months to three years from the commencement of their publication. Of the remaining number, twenty did not continue beyond five years, and of more than thirty now being published in this country, only thirteen have been in existence more than a single decade.

Comparing this experience in the establishment of journalism with that of other countries, we find that the instability is a peculiarity of our medical institution. As such, however, it has its peculiar causes and explanations, intrinsic as well as extrinsic. To the former the principal burden of blame attaches itself, the truth being that the management of medical journals has not been what it should be. We make this assertion in the full conviction that we ourselves are not infallible, and that in common with others, there is much room for improvement. But this is by the way.

We hold in the first place, that a journal of any kind that aims for popularity, should be conscientiously independent of every element or every influence save such as strictly serves the cause of truth. As a professional organ, it has eminently such a duty to perform, and in just so much as it does it, just in that proportion will its opinions be respected, and its reputation for probity earned. We believe that the majority of the journals have failed because they fell short of this requirement, by sacrificing their self-respect to cliquism, base puffery, to petty intrigues, and to the dictation of different medical schools. Not long ago a medical journal of this city, now extinct, claiming to be thoroughly independent, could not print a leading article unless the same was submitted beforehand to the approval of several prominent medical men, who would so often expunge certain statements of facts in fear of telling the plain truth, that when the article appeared in print its original writer could not recognize it as his. This was, perhaps, explained on the score that such gentlemen were very heavy stockholders in the concern, and were determined to use the periodical in their interests alone. We should be sorry to know that any other journals now in existence are given to the same policy. It is so easy, however, to drift into partiality, that it is sometimes wonderful to suppose that any paper can be above the considerations which lead to it—just as we sometimes amaze ourselves by contemplating a perfectly healthy body, against the usual chances for disease in any of its different organs. Colleges, cliques, and individuals are ever on the lookout to ventilate private grievances, and seek the mean and petty revenge of covert vilification through the columns of the journal. They are apt to bring all sorts of influences to bear against the good intentions of the conductor of the magazine; and often, under the penalty of non-patronage, insidiously beguile him into the interests of trickery, puffery, hypocrisy, and lampoonery. There is a great deal said about the freedom of the press; but to reduce the assertion to an absolute fact, very few periodicals can be found who dare at all times, and under all circumstances, to attack anything and everything that is wrong. And yet it is their bounden duty so to do, irrespective of the power of the parties concerned, the position they may hold, or the reputation they may have. A journal that calls itself strictly independent, is in the same relation to the medical profession as is an upright judge to the general community—neither has the moral right to betray the trust imposed.

Another inherent cause of failure is the lack of the requisite quantity and quality of contributions. When a journal is first started it is not difficult, on account of the prospective benefits, to the writer, of large circulations, to secure first-class contributions; but if the calculations of the editor do not go beyond the first few issues, he has often to beg for many an article which at first he had no hesitation in refusing. The difficulty of obtaining original material when the issue of the journal is trimmed to suit its bonâ-fide subscription list is sometimes so great as to compel the necessity of wholesale reprints from its contemporaries. But the failure to fulfil promises for good reading is not chargeable so much to the lack of a disposition to do what is right, as to the difficulty, nay impossibility, of keeping the majority of the enlisted contributors to their promises. The mistake in the majority of cases is in the small number of the contributing corps, no calculations being made for contingencies. This has been particularly the case with journals in small towns, limited districts, or from particular medical schools. On the other hand, too, in large towns where the material for contributions is abundant, and where the contributors are very many, there is frequently so little disposition to

write for periodicals that do not take a respectable stand, that they starve in the midst of plenty.

We are led in this connection to speak of the general scarcity of medical writers in this country. In no other community of medical men is there such a lack of desire to impart information with the pen. There are many hundreds of good, thorough practitioners in our midst, who, with an experience of twenty years and over, have never written a word for a medical paper. Is it fair to presume of these gentlemen that their experiences have been worth nothing to themselves or others; that they have discovered nothing that might be added to the common stock of professional knowledge? If such be their excuse for not writing, we commiserate their stupidity, and deplore the number of years they have spent for naught. How much more useful would such be, if, instead of entering our profession, they had devoted their energies to some respectable trade! But this is, in truth, not the main reason why such gentlemen are silent. We are convinced that a goodly number would be tempted to contribute their quota to the current medical literature, if they were properly qualified by previous education so to do. Alas! to the chagrin of the profession of this country be it said, the number of those who have enjoyed the privileges of a necessary preliminary education is disproportionately small to those who have not. Then add to this number those who, being able, are too indolent to write, and need we look further for a good explanation of the paucity of good contributions to our current literature?

Lastly, we come to consider the extrinsic causes of non-success. These are mainly summed up under one head—the want of proper pecuniary patronage. Generally speaking, the subscription list of a medical paper is much below that of any other strictly scientific publication. This is by no means due to the small number of physicians who should be interested in its success, but rather to the lack of the cultivation of a habit of reading and study. Probably not one physician in ten really imagines that he has any use for a medical journal, at least we can safely assert that not more than that proportion are supporters of our periodical literature. And yet we often hear such individuals denounce such publications as unworthy to represent the views of the profession. It has, seemingly, never occurred to them that they might have it in their power to turn the tide in favor of the journals by adding to the number on the subscription list, and contributing to the excellence of the original departments. But these reformers deny us the very opportunities for improvement which would place us beyond the necessity of their criticisms.

The medical department of the Prussian army has been much improved since the breaking out of the present war, and in effectiveness, numbers, and discipline, may perhaps equal that of any other similar organization. The Army Medical Staff is composed of regular surgeons and assistants to the amount of nine hundred, under the direction of a Medical Inspector General and staff, and about the same number of volunteer surgeons who are a provisional corps, and are ordered out only in times of war. These latter are styled Landwehr. The volunteer staff is further increased by a large number of young medical graduates, who serve in the different capacities of assistants. Besides this there prevails a system of medical cadetship. Two soldiers per company, having been instructed in minor surgery, are detailed as servants to the surgeons, and as general dressers for trivial wounds. In place of our ambulance corps, the Prussians have what are called sick-bearers, who now number five thousand.

The French medical staff has undergone equally radical changes. There is a large accession of civilians to the regular army corps, and from all accounts they are rendering, under the direction of their Sanitary Commission, very effective service. The number of cadets recruited from the medical schools is very large.

Both armies are, surgically speaking, well comparisoned, and despite the rumors and assertions to the contrary, carry on their operations upon the broad and humane conception of treating all the wounded and sick of either side upon terms of the strictest neutrality. The principle of action is founded upon the international treaty of August 22, 1864; the Prussian and French governments being alike parties to the same.

The first article of this treaty provides, that ambulances, hospitals, and all material destined to aid the sick and wounded, either on land or sea, are recognized as strictly neutral. The members of the societies of relief for wounded soldiers in the land and naval services of every country, their attendants, material, as well as volunteer aids and nurses, and the convoys of the health service, are likewise protected. The members of these societies wear a badge, which is a red cross upon a white ground. This badge must be respected wherever seen. Even the habitations in which wounded soldiers are cared for have full and complete protection. There are also minor matters providing for the recognition of the wounded, their protection from pillage and bad treatment; the recognition and burial of the dead; preserving the identity of the soldier; the completion and transfer of lists of sick, wounded, and dead; but these show the broad humanity and generous treatment of wounded belligerents, which, originating in the Sanitary Commission of the United States, now characterize all the armies of civilized nations. The organization of the Prussian Medical Service, particularly its hospital organization, is one of the most complete in the world. Every corps is provided with material and nurses necessary for three field hospitals and three ambulances, besides a competent medical corps and detachment of troops specially detailed to take up the wounded and remove them to the ambulances or temporary hospitals. Furthermore, they allow voluntary aids (who wear the international badge upon the arm) to keep close up to

the battle-fields; they encourage the gifts of the people for succor to the wounded, and they have fitted up immense trains of hospital cars upon the railways.

It is pleasing, in view of all the dreadful slaughter which this present war entails, that a noble and enlightened humanity accomplishes all that is possible in alleviating the sufferings of the sick and wounded.

Reviews and Notices of Books.

MEDICAL DIAGNOSIS, WITH SPECIAL REFERENCE TO PRACTICAL MEDICINE. A Guide to the Knowledge and Discrimination of Diseases. By J. M. DA COSTA, M.D., Lecturer on Clinical Medicine, and Physician to the Pennsylvania Hospital, etc., etc. Third Edition, revised. pp. 844. Philadelphia: J. B. Lippincott & Co. 1870.

THE author has divided the work into thirteen chapters. The first, which may be regarded as introductory to the rest, is devoted to the examination of patients and some symptoms of general import, and occupies nearly fifty pages. In regard to the significance of general symptoms, much importance is attached to the different kinds of pulses:—"A hard, full, frequent pulse occurs in active inflammations, and in most of the acute diseases of robust persons. A hard pulse, full or small, bounding or not, if unconnected with acute symptoms, leads to the suspicion of cardiac disease, or of an affection of the artery itself. A tense, contracted, and frequent pulse is met with in a large group of inflammations below the diaphragm: as in enteritis, peritonitis, gastritis. A frequent pulse, full or small, but rarely tense, is the pulse of most idiopathic fevers. A very frequent pulse, but very feeble and compressible, is the pulse of marked debility, of prostration, of collapse. A pulse frequent, and changeable in its rhythm, is produced, for the most part, either by disease of the heart or of the brain." The *sphygmograph* of Marcy, with the improvements of Austin and Sanderson, is a very ingenious instrument for examination of the pulse with precision; but the author rightly agrees with the majority of the prominent investigators and authors, that the precise value of the instrument for clinical research is yet to be fixed. At all events, it does not yet supersede the older and more usual means of research.

The difficult and important diseases of the brain, spinal cord, and their nerves, are as clearly defined in Chapter II. as the deficient knowledge of the physiology of these vital parts, and the ability to appreciate the minute structural changes of nerve-tissue, will allow. In discussing this chapter, we will allude to the essential points hinted by our author on the subject of *anæsthesia*, that his position may be understood:—

"In endeavoring to form a correct opinion of the completeness of anæsthesia, it will not do to trust entirely to the patient's statements. We must resort to means by which we can make accurate comparison; and one of the best is to pursue the method used by Weber in his researches on the tactile properties of the skin. It consists in determining how closely the points of a pair of compasses, sheathed with cork, may be approximated on the skin, and yet be felt as two distinct points. An instrument for the same purpose, called the æsthesiometer, was invented by Dr. Sieveking, and can be applied in paralysis to ascertain the amount and extent of sensational impairment, as a means of diagnosis between actual paralysis of sensation and mere subjective anæsthesia in which the tactile powers are unaltered, and as affording us assistance in determining the progress of a case of palsy for better or for worse." Two other useful instruments have been invented by scientific observers; the one used by Brown-Séquard, with a larger handle; the other combining the principle of the beam compass with that of the mathematical one, contrived by Dr. Ogle.

A short but comprehensive chapter follows upon diseases of the upper air passages, and the application of the *laryngoscope*.

The clearness with which he makes his statements in regard to the best means of making a laryngoscopic examination, shows the author to be a practical manipulator; the subjoined opinions are entitled to consideration:—

"In some persons with very irritable throats, I have obtained good views by pressing the instrument against the roof of the mouth, instead of passing it back into the pharynx, and by altering the position of the head a little, tilting it more backward. The epiglottis, and the structures at the entrance of the windpipe, are thus readily enough brought into view; with the deeper parts we do not succeed so well. But in many cases we get sufficient guide for topical applications.

"There are some further obstacles, such as rising up of the tongue, greatly enlarged tonsils, a very long uvula or a pendent epiglottis, all of which at times seriously interfere with our investigations. But in any case we should not endeavor to make the view more satisfactory by constantly altering the position of the mirror. It is always better to introduce it repeatedly, than to shift it often when introduced, or to keep it for any length of time in the patient's mouth."

To acquire dexterity and quickness of manipulation, one of the best means in our possession is *autolaryngoscopy*. We may readily inspect our own larynx by the simple method recommended by Dr. George Johnson, by employing a toilet glass and throwing the light, with the reflector worn in the ordinary manner, on the image of the fauces as seen in the toilet glass; the laryngeal mirror is then introduced into the mouth.

In Section third of Chapter VI., an exhaustive inquiry is made of the symptoms which the disease of the liver generally manifests: 1st. One of these is pain; generally dull, radiating from the seat of the liver. 2d. The usual accompaniments of hepatic affections are *digestive troubles*. 3d. *Disturbance of the portal circulation* is also a very frequent consequence of disease of the liver.

Under rare circumstances *cancer of the stomach* may simulate cirrhosis. To illustrate this point, the author reported in the *American Journal of Medical Sciences*, vol. lii., 1866, a case which came under his care at the Pennsylvania hospital, where, with very slight digestive symptoms and without discernible epigastric tumor, considerable ascites and effusion into the left pleural cavity existed. The bowels were loose, and bile pigment was present in the urine. This case might have been selected as cirrhosis of the liver, as the man had been very intemperate; yet at the autopsy the liver was not cirrhotic, although small and rather hard, and a cancer, involving nearly the whole stomach, excepting the pylorus, was discovered.

A large portion of the work is taken up with the pathological and clinical aspects of the urine, and on other diseases of the urinary organs. In the discussion of the several tests of the urea, Davy's method, with hypochlorite of soda or Labarraque's solution is to be preferred to Liebig's process. With the imported French solution, it has the sanction of Professor Austin Flint, Jr., of New York, who asserts that, with the American article, it is very uncertain. For all ordinary purposes the rough way of estimating the urea—by dropping nitric acid into a porcelain capsule holding urine which has been evaporated to a mucilaginous

consistence—is recommended. He also adds, that we may often, even without subjecting the fluid to this test, guess that the urea is increased by observing the deep-yellow color, the strong urinous smell, and high specific gravity of the discharge. The attention which the study of urinary diseases is receiving will insure a thorough examination of this entertaining chapter of nearly one hundred pages. The last section, on poisons and parasites, is made very instructive and interesting, but we have occupied so much space in hinting at some of the most prominent points of the work, that we shall leave the rest to the reader.

In conclusion, we take occasion, but not for the first time, for expressing our appreciation of the author's labors, and commending them to the attention of every medical practitioner throughout the land. The wood-cuts employed are all original, and executed in a high style of art; many of them are improved by the skilful hand of Dr. Packard, and they combine all that can be desired in medical illustrations.

It is handsomely printed on fine tinted paper, and the text is unusually free from inaccuracies.

STRONG DRINK AND TOBACCO SMOKE. The structure, growth, and uses of malt, hops, yeast, and tobacco. With one hundred and sixty-seven original illustrations, drawn and engraved on steel. By HENRY P. PRESCOTT, F.L.S. New York: William Wood & Co. 1870.

THE origin of this work was an attempt to popularize, by means of public lectures, the study of botany, and especially the structure of plants and their mode of growth. For this purpose the author judiciously selected a few plants of general interest, because in some form or other they are very largely consumed nearly all the world over. With the physical and moral effects of this consumption of alcohol and tobacco, the author has nothing whatever to do. He confines himself strictly, in the first place, to a description, very clear and complete, of the materials entering into the composition of beer and spirits, and of the various articles used in adulteration. The growth, nature, and minute structure of barley and hops, and the conversion of the former into malt, are very fully described and illustrated. The yeast plant is next taken up, and this leads naturally to the method of manufacturing beer and whiskey. These subjects occupy six of the seven chapters which compose the book. The seventh is devoted to the tobacco plant, and the means, microscopic and other, of detecting the various "weeds" and other substances used in adulterating the tobacco of commerce. Those who consume this drug in any shape may easily learn to judge for themselves of its purity.

No one can carefully peruse this interesting volume without acquiring a considerable knowledge of vegetable anatomy and physiology, to which the beautiful plates and illustrations contribute largely. The book is edited by Professor Huxley.

A GUIDE TO THE EXAMINATION OF THE URINE, for the Practitioner and Student. By J. WICKHAM LEGG, M.D., Member of the Royal College of Physicians, Physician to the St. George, Hanover Square, Dispensary. Second Edition. Lindsay & Blakiston, Philadelphia. 1870. 12mo., pp. 88.

THIS little work is designed to be a practical guide for the microscopical and chemical examination of the urine; and well does it meet such an end. All the information that is necessary to the chemical student, hospital interne, and general practitioner, is given concisely, systematically, and clearly. Especially is this true with regard to the urinary deposits, their microscopical character, chemical reactions, &c. A very useful and reliable appendix has been added, in which the manner of estimating the urea, chlorides, phosphates, sugar, etc., by volumetric or other rapid analysis, is described. We unqualifiedly recommend the book to every one who desires to become practically familiar with urinary examinations. We can look back to the time when such a work as the present one would have been an invaluable aid to our early microscopical and chemical studies.

THE RETROSPECT OF MEDICINE, being a half-yearly journal, containing a retrospective view of every discovery and practical improvement in the Medical Sciences, edited by W. BRAITHWAITE, M.D., late Lecturer on Midwifery and the Diseases of Women and Children, at the Leeds School of Medicine, etc., and JAMES BRAITHWAITE, M.D., Lond. Vol. LXI. January–June. London, Simpkin, Marshall & Co. Edinburgh, Oliver & Boyd. Dublin, Hodges & Smith. 1870, 12mo. pp. 400.

The foregoing number of this journal (which we have just received from the editors) contains more than the usual number of well selected and valuable materials.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

STATED MEETING, SEPTEMBER 14, 1870.

DR. J. C. HUTCHISON, PRESIDENT, in the Chair.

THE Committee on Microscopy reported the tumors of the liver in Dr. Merritt's specimen of liver to be tuberculous in character.

CANCER OF PYLORUS.

DR. FINNELL exhibited a specimen of cancer of the stomach on behalf of Dr. Hogan. The subject from whom it had been removed was a female aged fifty-five, who had suffered for six years previously with dyspeptic symptoms. She had very severe attacks of what appeared to be acute gastritis accompanying her other symptoms. On entering St. Vincent's Hospital she was found to be suffering from all the usual symptoms of a disturbed stomach, vomiting, distress, and inability to retain any food. Her ingesta would pass seemingly as far down as the pyloric orifice, when they would be immediately rejected. Death finally occurred as the result of inanition. At the autopsy a deposit of cancerous material three inches in depth was found around the pylorus, constricting the orifice at that point to the diameter of a small-sized probe. The mother of this patient had died of the same disease, in the same locality, at the age of fifty.

DESTRUCTIVE INFLAMMATION OF ANKLE-JOINT—AMPUTATION.

A second specimen by Dr. Finnell was the lower extremity removed by amputation from a man aged thirty. Six months ago he first noticed pain and stiffness in the right ankle when he walked. The part soon after commenced to swell, and in consequence of this and the increase of his pain he was confined to his room. The swelling, which was more on the right than the left side of the leg, finally culminated in an abscess over the extremity of the fibula, which opened spontaneously, discharging unhealthy pus. After a few weeks an abscess formed over the internal malleolus with a like result, and also one on the anterior surface of the joint. All this occurred within one month of the first appearance of the swelling. An attempt was made to treat the patient by perfect quiet of the limb in appa-

ratus, but the pain was so severe that the plan was abandoned in despair. Dr. Finnell finally saw him as an out-patient, and, in view of existing pulmonary disease, the rapidity of development of the joint affection, and the severe constitutional disturbance, advised amputation. It should also be mentioned that a thorough examination of the joint showed its surfaces denuded, with other evidences of extensive and rapid disorganization. Aside from this, one of his wrist joints was commencing to be similarly affected. Amputation was performed at St. Vincent's Hospital, September 10, with the result, up to the time of reporting the case, of an amelioration of all his general symptoms.

On cutting into the joint it was found to contain unhealthy pus, its surfaces were reddened and pulpy, the extremities of the bones were softened and in places partially denuded. All the abscesses communicated with the ankle-joint.

CHRONIC FLATUS. ENORMOUS LOCALIZED DISTENTION OF PORTION OF ILEUM.

A third specimen by the same gentleman was exhibited on behalf of Dr. J. W. Wright, and was a portion of the ileum, fifteen inches in length, removed from a carman, aged fifty, who had suffered for the past sixteen years with dyspepsia and occasional attacks of violent colic with flatulent distention. The only relief obtained from the latter was by large doses of cathartics. During the month of July, Dr. Finnell saw the patient, in one of his colics, in consultation. The abdomen was then enormously distended and tympanitic, and all the other symptoms were those of internal strangulation. A diagnosis was made accordingly. He died at the end of eight days from exhaustion, the result of obstinate vomiting and continued pain.

At the autopsy the cause for the enormous distention was found in the condition of the section of ileum presented. As before mentioned, it was fifteen inches in length and had seemingly been twisted at each extremity, so that the confined gas had distended it at its largest point to a diameter of eight inches. The upper twist was gangrenous, the result of post-mortem decomposition. The coats of the diseased portion were much thickened, and the whole presented the shape and general appearance of a good-sized stomach. There was no peritonitis anywhere. No feculent matter was found in the sac or in its neighborhood; and there were no evidences of localized inflammation of the gut at the point involved in the lesion.

Dr. F. V. White asked if such a condition of things was not an anomaly in pathological anatomy. Dr. Finnell stated that Jones and Sieveking referred to it as occasionally occurring. Dr. Rogers had not met with any precisely similar cases in his reading, although in searching up the literature of intestinal affections for another purpose he had met with instances of localized distention from membranous bands, adhesions to contiguous parts, and intussusceptions.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

STATED MEETING, SEPTEMBER 5TH, 1870.

DR. ELLSWORTH ELIOT, in the Chair.

IN the absence of the President and Vice-President, Dr. Ellsworth Eliot was, on motion, appointed to preside.

The Secretary stated the fact of the illness of the President during the adjournment of the Society for the summer.

The President *pro tem.* announced the admission to membership of Drs. J. W. S. Gouley and Chas. Bliss; also the death, since the last meeting, of Dr. Gunning S. Bedford, a member since Sept. 14, 1831; Dr. Thaddeus M. Halstead, a member since Feb. 26, 1839; and Dr. John Shanks, a member since March 13, 1837.

The report* of the Committee on Intelligence was read by Dr. B. S. Thompson.

DR. FINNELL, in a few appropriate remarks, made mention of the decease of Prof. Bedford. He then presented a very rare and interesting specimen of Diverticulum from the intestinal canal. Remarks on the same were made by Drs. Jacobi and Rogers.

DR. JOHN C. PETERS showed maps of the course of all the epidemics of Cholera.

DR. JACOBI presented the following resolution, which was unanimously adopted:

Resolved, That this Society has heard with sorrow of the illness of its President, Dr. Geo. T. Elliot; and, while regretting that he is unable to be with us at this time, we rejoice at the prospect of his recovery, and hope that he will soon be able to resume his labors, which added so much to our prosperity and made his name known as an accomplished scholar and skilful physician.

The following addition to Chapter I. of the By-Laws of the Society was recommended for adoption at its next anniversary meeting:

CHAPTER I. ARTICLE —.

"Members whose dues are unpaid shall not be candidates for any official position in the Society, nor shall they be entitled to vote."

Nominations were then made for all the regular officers, as well as for twenty-one delegates to the State Society. (The election will be held at the Anniversary Meeting, on the first Monday in October.)

The Society adjourned.

CANADA MEDICAL ASSOCIATION.

THE Medical Association of the New Dominion met on the 14th ultimo, in Ottawa. The American Medical Association was represented by Dr. Storer, of Boston, Dr. Garrish, of New York, and Dr. Sullivan, of Malden, Massachusetts.

The opening address was delivered by the Hon. Dr. Tupper, President. After alluding to the good that had been accomplished by the Association, he reviewed the action of the previous meetings. A committee was appointed at the last meeting to prepare amendments to the Medical Bill. It was admitted that such a measure must be compromised. They had agreed on the appointment of a General Medical Council appointed by the schools and by the medical men of the country. They had also agreed on the common legislation for all the Province, in punishing men for practising without medical education, but it would not do to go beyond public sentiment. He would leave it open to all to employ whom they pleased, but would impose a heavy penalty where persons were guilty of deception in representing that they had authority to practise.

At the afternoon sitting, papers on medical subjects were read by Dr. Sheriff and Dr. Kingston.

Dr. Howard then read the draft of the Medical Bill, as proposed by the committee.

There are forty-nine sections in the bill. It is very similar in its provisions to the Ontario Medical Act, ex-

* This interesting report, for want of space, is deferred until our next issue.—ED.

cept that no reference is made to Eclectics or Homœopaths, who are thus completely ignored.

The Medical Council will be composed of representatives of the Universities, and twelve men from the registered members of the profession—four from Ontario, four from Quebec, and four from the other Provinces. Branch Councils for the several Provinces are provided for.

The discussion of this bill was the principal business before the meeting.

The first clause of importance was that providing for the admission into the College of Physicians and Surgeons of Canada, of every person at present holding a license to practise. This clause was adopted.

The next clause eliciting discussion was that providing for representatives in the General Medical Council. After a good deal of discussion it was Resolved—"That no University or College that does not exercise Medical functions by a staff of Teachers or Board of Examiners regularly conferring medical degrees, shall be entitled to representation in the Council." This clause was carried by a majority of one.

It was further resolved that the General Council shall be composed of thirty members—ten representing Ontario; ten Quebec; and five Nova Scotia and New Brunswick, respectively, in accordance with the following plan: Each school of medicine or University having a staff of teachers or a board of examiners regularly conferring degrees, shall have the privilege of sending a representative to the General Medical Council, and the remainder shall be elected by the members of the College of Canada not connected with the teaching or examining bodies.

The next important step was the abolition of the clause providing for branch councils, as also of that providing for branch Examining Boards; it being determined to have one central examining board.

The next decision of importance was that no medical school, other than those now in actual operation, shall be recognized after the passing of this Act, unless its recognition shall meet the approval of the General Medical Council.

A discussion then arose regarding a personal clause inflicting a fine upon persons wilfully and falsely pretending to be possessed of the legal requirements entitling them to practise. It was then agreed that in default of the payment of the said fine, any such person should be sent to jail for the period of 30 days.

The Bill, as modified, was referred to a committee to incorporate the amendments and superintend the printing. It will come up for consideration at the next annual meeting, and will then be finally disposed of by the Association.

An interesting paper on Entozoa was read by Dr. Van Cortlandt.

Hon. Dr. Parker, of Halifax, was elected President for the ensuing year, and Quebec designated as the place of the next annual meeting.

The Association adjourned on the 17th.

NEW YORK MEDICAL JOURNAL ASSOCIATION.

STATED REUNION, MAY 27, 1870.

DR. ISAAC E. TAYLOR, PRESIDENT, in the Chair.

ANTIPHLOGISTICS IN DISEASES OF CHILDREN.

DR. JACOBI continued his remarks upon this subject, of which we give a report on page 337.

DR. A. H. SMITH.—Dr. Jacobi's remarks upon the use of ergot suggest a case recently reported to me by a highly intelligent physician of this city. A woman, after delivery, had much blood left in the uterus, and spasm followed. To combat this, fluid extract of ergot was given, to the extent of about an ounce in twenty-four or thirty-six hours, with the effect of expelling a large amount of blood partially decomposed. Within forty-eight hours of the time the last dose was given the woman began to complain of diminished sensibility, pain, and coldness in the extremities; and it was found that the pulse was almost absent there, while in the carotids it was at sixty. The toes became very blue, and a line of gangrenous demarcation was beginning to be foreshadowed. By very vigorous use of quinine, wine, and the inhalation of oxygen, reaction was brought about, being fully established by the third day. The blood-poisoning, which had taken place to some extent, would approximate the case of this woman to that of the badly nourished persons mentioned by Dr. Jacobi as especially liable to the injurious effects of ergot.

A word also with regard to the use of alcohol as an antiphlogistic, especially in cases of pneumonia. Its effect in reducing the temperature is unquestionably produced by its retarding tissue-change. It is well known that alcohol diminishes the amount of carbonic acid exhaled from the lungs, and there is no doubt that retrograde metamorphosis is diminished in the system generally. Now, although alcohol may act as a local irritant, yet we should also, I think, take into account the lessened demand upon the lungs resulting from this diminished elimination of carbonic acid, and the consequently diminished respiration. This may, perhaps, relieve the lungs enough to counterbalance the local irritation.

DR. MESSENGER.—Bonjean says that he has succeeded in removing the poisonous principle of ergot, and that large doses of his "ergotine" will not cause gangrene as would ergot itself. Taking this into account, I gave it in large doses in a case of hemorrhage from the bladder. The patient was a weak old man of upwards of seventy years, very anæmic from having lost a great deal of blood, and much reduced in every way. After I had resorted to all the measures I could think of to arrest the hemorrhage, ergotine was suggested to me by an apothecary. I had then, two years ago, no experience with the preparation. I gave half-drachm doses in solution every four hours, and also used it locally by means of a double canula and catheter. After a while I succeeded in stopping the bleeding, and there was nothing of the injurious effect which might naturally have been expected from the ergot. So perhaps Bonjean is correct in his claim.

I think the good effects of ergot in inflammatory diseases are not so generally known to the profession as they ought to be. Judging at least by the slight mention to be found in the journals, too few are aware of its great value in a considerable variety of affections, particularly diarrhœa, dysentery, and fluxes of almost every kind.

DR. JACOBI.—In the case related by Dr. Smith, I do not feel entirely satisfied that the cyanotic hue of the lower extremities was the result of the doses of ergot given. Might it not be possible that the woman was simply in imminent danger of dying, except for the resuscitation by stimulants, quinine, etc.? Was not the color the premonitory symptom of death rather than of local gangrene?

THE DISCOVERY OF GALEZOWSKI.—This investigator has found syphilitic retinitis and neuritis to be always accompanied by color-blindness.

Correspondence.

INDURATION OF SPINAL CORD AND SCLEROSIS.

To the Editor of the Medical Record.

Sir—In The Record of September 15, p. 324, I read: "I. Netten Radcliffe, M.D. (*Med. News and Library*), in his paper on 'Diseases of the Spinal Cord,' remarks, 'Like the opposite condition of softening, induration (sclerosis) of the spinal cord is one of the consequences of myelitis, acute or chronic, the chronic form especially . . . is generally associated with atrophy, more marked in the white matter than in the gray, with a condition so curiously bloodless that a section is not unlike that of white of egg. . . . It has no symptoms by which it can be distinguished from softening, etc.'" These sentences, so full of errors of statement of facts, were not written by Mr. I. Netten Radcliffe, late Superintendent of the Hospital for the Epileptic and Paralyzed, London, but by Dr. C. B. Radcliffe, and appear in one of his articles on "Diseases of the Spinal Cord," *Reynolds' System of Medicine*, vol. ii., p. 668, and which are reprinting in the periodical to which they are credited in The Record as an original contribution. The identification of induration and sclerosis of the spinal cord, two distinct morbid conditions, is so misleading, clinically and pathologically, and so at variance with present views which hold sclerosis to be a special alteration, and entirely distinct from induration of the cord, that this untrue information should not have currency by means of your widely circulated journal, without notice and correction. To point out all the mistakes and ignorances of the quoted lines would occupy more space than you would be willing to grant, and more time than I am disposed to give, as I have already, both in the columns of The Record and elsewhere, endeavored to show what sclerosis of the cord in its several forms is. I will, therefore, only indicate one of the most remarkable and mischievous of these wrong statements, namely, that softening of the cord cannot be "distinguished" from locomotor ataxy (posterior sclerosis), or from disseminated sclerosis with its fits of tremor, or diffuse peri-ependymary sclerosis, etc., none of which have symptoms in common with softening of the nervous centres.

I should, perhaps, state that the articles now reprinting in the *Medical News and Library*, from which the extract is directly made, were written some years ago, before the recent investigations of continental histologists were generally known in England, and that in the second and revised edition of vol. ii. of *Reynolds' System*, soon to be issued, we shall most likely find the chapters on "Diseases of the Spinal Cord" more abreast with the knowledge of the day than in the first.

Very faithfully, your obedient servant,

Meredith Clymer, M.D.

135 Lexington av., New York, Sept. 26, 1870.

THE TREATMENT OF MALIGNANT TUMORS BY ELECTROLYSIS.

To the Editor of the Medical Record.

Sir—Since the publication of my first case of successful treatment of a malignant tumor by Electrolysis,* I have received a great many letters upon the subject from physicians in different parts of this country and of Europe. Almost all refer especially to two points—namely, the subsequent fate of my first patient, and whether other cases have confirmed the correctness of my views with regard to the efficacy of the electrolytic treatment of malignant tumors. To these two questions I am now able to give a positive answer.

It will be remembered that my first patient had been examined by most distinguished surgeons in Europe and America, who all declared him to be affected with a general cancerous diathesis. After the extirpation of his tumor in the left mammary region, the axillary glands of the same side became affected, and were subsequently also removed by a surgical operation. The extirpated tumors were examined microscopically in Paris and New York, and found to be real cancers. Finally, a third tumor developed itself in the right mammary region, which entirely disappeared after my electrolytic treatment in April, 1869. From that time no new cancerous deposits appeared anywhere, and the general health of the patient, which was in an alarming condition before the electrolytic treatment, became excellent in all respects. The patient continues to do very well, now a year and a half after the electrolytic treatment.*

Since May, 1869, I have treated with the same happy result eleven other patients affected with malignant tumors, almost all of them scirrhous. In some of these cases surgical operations had been already performed previously, and the extirpated tumors presented the microscopical appearance of cancer. All the cases exhibited signs of malignancy by their consistency, or by the character of the ulcerated surface, and by the affection of the lymphatic glands. In all these cases, the detailed history of which will be given hereafter, the tumors entirely disappeared after the electrolytic treatment, and no new deposits could be detected anywhere.

I have lately considerably improved the electrolytic method, so as to make it less painful and to shorten the time of treatment. But even during that time, the patient continues his usual pursuits and mode of life, as the treatment is not accompanied by fever or any other constitutional or local disturbance. To avoid hasty generalizations, however, and not to discredit the method, which certainly is destined to be of the utmost importance in the treatment of malignant tumors, I was careful in selecting my cases, and limited myself to the treatment of such malignant tumors as presented a hard consistence, and were of slow growth. From my present experience I have every reason to draw the following conclusions with regard to such scirrhous tumors:—

1. That the electrolytic treatment is able to destroy malignant tumors in a harmless way.

2. That electrolysis is not only a local remedy, but also a powerful constitutional agent, capable of curing the diathesis and preventing relapses.

3. That malignant tumors ought not to be removed by the usual surgical operations, as these do not prevent relapses, and only hasten the generalization of the disease and its fatal termination.

At the request of some medical friends I brought this subject before the American Medical Association, on the third day of its meeting in Washington. Unfortunately, the attendance on that day was very small, but few surgeons being present, and probably no phy-

* Medical Record, Sept. 1, 1869.

* In one of his last letters to me he writes: "I feel that to you far more than to any other mortal am I indebted for the preservation of my life through the fearful perils of erysipelas and attendant fever, and to you also must I ascribe the dispersion of the cancerous tumor in my right side by your electrolysis. You told me you believed you could destroy it, and you did so. Absorption had proceeded to a very considerable extent before I left you, and continued until the breast became perfectly natural."

sicists. One of those present denounced this method, on the ground that he used the same apparatus with which I work, and yet with an utterly negative result. But from what he said, it was evident that he was not familiar with the elements of physics, and had used the anode, which he mistook for the cathode. Of course none but a negative result could have been expected from such experiments. Certainly the fact that my first communication has been published in *Virchow's Archives*, and reprinted in a great number of medical journals of France, England, Italy, and other countries, and has been quoted and favorably commented upon in the *Centralblatt für die Med. Wiss.*, *Virchow's Jahresbericht, &c.*, might have been a sufficient guarantee of the importance of the subject, even to those not acquainted with Physics and Electrophysiology.

In my work on the Galvanic Current, which will soon appear, I shall give a detailed account of the modified method which I am using, together with authentic cases, and my views concerning the development of malignant tumors.

I have no doubt that the electrolytic method will soon be found by competent and impartial judges to be a valuable contribution to surgery, in the interest of which I have undertaken these researches.

W. B. Neftel, M.D.

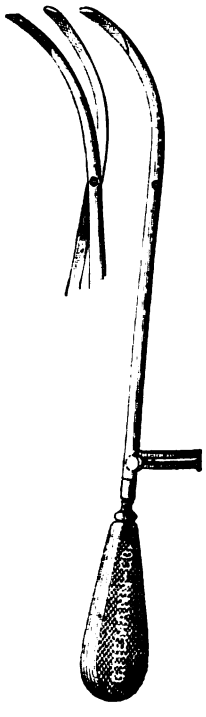
New Instruments.

A NEW UTERINE SOUND AND SCARIFICATOR.

By ALEXANDER J. C. SKENE, M.D.,

PROFESSOR OF DISEASES OF WOMEN AND CLINICAL OBSTETRICS, IN THE LONG ISLAND COLLEGE HOSPITAL.

In the treatment of diseases of women I have experienced no little trouble in finding a convenient instrument for scarification of the uterus.



A plain straight, or curved knife, would not answer all the requirements, and the complicated uterine scarificators, while they more nearly answered the purpose, were open to some objections.

The best instruments which I have seen, heretofore, are those of Drs. Storer, Miller, and Pinkham, but I could never acquire facility in using them, and they required more time to keep them clean than I could afford.

I had often wished—while exploring the cavity of the uterus—that I could transform the probe-point of the sound into a cutting edge, so that I might scarify with the same ease that I could examine. This idea, and necessity, led me to devise the instrument here figured.

Its shape is like an ordinary sound, divided longitudinally into two equal parts, one of which is probe-pointed, and fixed into the handle; the other—a little the shorter—is made at the end like a pointed bistoury. The two halves are held together, like the blades of a scissors, by a button, and when the blades are closed it looks exactly like a uterine sound or probe. Its convex border is marked by small notches, an inch apart, for measuring the size of the uterine cavity. When the blades are closed it can be easily introduced into the cavity of the cervix or body of the uterus, and by pressing on the end of the cutting blade its sharp point is thrown forward for the purpose of scarification, as shown in the figure.

The button which holds the two halves together is so arranged, that, by turning the blades at right angles to each other, they can be taken apart, washed in a moment, and placed together again with the greatest facility.

Having used this instrument for two years in a large hospital practice, experience warrants me in saying that it answers all the purposes for which the uterine sound is used, except that it cannot be bent to suit all cases as the flexible copper sound can be. As a scarificator it fulfils all requirements; the incisions can be made at any point in the cavity of the cervix, or body, and the cutting blade can be regulated so as to cut any depth required. When free depletion is desired the cutting blade can be taken apart from the other, and used to puncture the vaginal portion of the cervix—a favorite practice with some. It is also a valuable uterotome, and can be used in performing Dr. Emmet's operation for flexion of the uterus. After dividing the cervix up to the vaginal junction the angle formed by the flexion at the os internum can be divided easily and accurately with it.

After use the instrument can be thoroughly cleaned in a very short time, which is a valuable quality for anything used in uterine surgery.

The instrument is manufactured by Tiemann & Co.

Progress of Medical Science.

Apoplexy.—Dr. J. M. Da Costa, in his *Medical Diagnosis*, makes the following queries in regard to the cause of apoplexy:—

Now, is there anything at the time of the apoplexy, or after its most urgent symptoms have passed away, by which we can recognize whether the pressure on the brain results from a clot, a serous effusion, or from a turgescence of the cerebral vessels? And, again, do the morbid manifestations furnish any clue to the seat of the hemorrhage? With reference to the former question, all clinical experience forces us to admit that, in any of the states mentioned, the actual signs may be the same; and that we never can be quite certain of the non-existence of a clot. It is true that when the apoplectic symptoms abate rapidly; when thought, however confused, soon returns; when the limbs are not paralyzed, or are so but imperfectly and for a short time,—we have strong reason for believing that congestion simply lies at the root of the disturbance; that, in other words, the case is one of those called simple apoplexy. But it is never possible to give a positive opinion, since a clot near the periphery of the brain may occasion the same phenomena as those specified.

And with regard to a rapid effusion of serum, the difficulty of distinction is quite as great, or even greater.

The *seat* of the hemorrhage can ordinarily be detected with somewhat more certainty than the cause of the cerebral pressure; it could be detected with yet greater certainty, were it not that the extravasation so often takes place into an already diseased brain.

Sciatica.—This affection is rare in children, being the most frequent between the ages of twenty and sixty. Drs. Valleix and Fuller state it to be more common in men than in women, which is denied by the late Dr. Copland, and Dr. Romberg.

An Excellent Way of Finding Lung Tissue.—Dr. Fenwick (*Medico-Chirurg. Trans.*) finds the characteristic lung tissue of phthisical patients, in the sputum as follows: Liquefy the sputum with pure caustic soda, when any particles which may be contained in it fall to the bottom of the vessel, and can be easily removed and placed under the microscope.

Pulmonary Fetor.—Dr. Laycock (*Edinburgh Med. Jour.*) asserts that there are three distinct kinds of pulmonary fetor—that of ozæna, that of fæces, that of gangrene. The latter, due to putrescent decomposition of pulmonary tissue, is characteristic of true gangrene. The ozæna odor is connected with chronic tissue changes of rheumatic origin, as with fibrinous exudation and degeneration. It is found chiefly in fetid bronchitis and bronchorrhœa, and in fetid fibroid vomicæ. The fecal odor may also be observed under these circumstances, and has too, probably, a rheumatic origin.

One Cause of Flatulence.—As a cause of flatulence and eructation which it is important not to overlook, thoracic aneurism may be mentioned.

A Peculiar Form of Hæmaturia.—There is a form of hæmaturia which is endemic, and depends upon the presence of a parasite (*Bilharzia hæmatobia*). It prevails in the Mauritius, certain parts of the Cape of Good Hope, Natal, Egypt, and Brazil. The parasite inhabits chiefly the small vessels of the mucous membrane of the urinary passages and the kidneys, and it gains access to these parts chiefly during the act of bathing in the rivers. Persons afflicted with the Bilharzia hæmatobia are often observed to pass small renal calculi of oxalate of lime, which have for their nuclei the ova of this parasite.

Chronic Bronchitis in Bright's Disease.—This is one of the most common complications of Bright's disease; so common that Rayer observed it in seven-eighths of his patients, and Wilks states it, from an extensive analysis of cases, to have been more universal than any other single symptom, albuminous urine alone excepted.—*Guy's Hosp. Reports.*

To Detect Uric Acid in the Blood.—Dr. Garrod's ingenious plan of detecting uric acid, which is always in great excess in gout, is as follows:—It consists in obtaining the crystals of uric acid on a thread placed in a mixture of the serum of the blood, or of the fluid from a blister, with acetic acid, in the proportion of six minims of the acid to each fluid drachm of the serum.

Time of Appearance of Iritis.—Iritis occurs at every time of life. It often destroys the good result of an operation for cataract in the most advanced old age, and it is also observed in the newly-born. There are even recorded experiences which render possible the belief in an iritis occurring during fœtal life. The middle period of life, from the 21st to the 40th or 50th year, certainly furnishes the greatest percentage. This may be in part due to the greater frequency of traumatic influences and constitutional syphilis at this time of life. Sex seems to exercise no peculiar influence upon the mild or severe course of an iritis. Whether the left iris and irides of a dark color are more disposed to the affection, as some believe, is not yet sufficiently decided.—*Stellwag on the Eye.*

Shortest Time in which Perception of Color can be effected.—Vierordt, and two of his pupils, Burkhardt and Faber, have made experiments on the shortest time in which a perception of color can be effected. They passed stained glasses more or less rapidly before the eye. The intensity of illumination was varied by moving the same kerosene lamp behind a screen of ground glass, which itself illuminated the stained glass. The duration of the retinal impression was measured by means of a pendulum swinging before a slip-shaped opening, of a given but variable breadth. The shortest time required to produce a sensation of color was 0.0029 second, and the intensity of illumination was 21 to 50 times as great as is necessary to recognize the color when looked at for an indefinite period. It seemed that different colors required about the same intensity of light to be perceived at the shortest possible time (*Pflüger's Arch. of Physiol.*, II. p. 121).

The dark appearance of the background of the eye in the region of the yellow spot, is explained generally by the larger amount of choroidal pigment, but according to T. W. Hulke (On the Anatomy of the Fovea Centralis Retinæ, *Phil. Trans.*, 1867) by a diffuse stain of the retinal tissues, and according to E. Taeger (*Ophthalmoscop. Hand Atlas*, 1869, p. 33) principally by the diminution of the intensity of light in this place, on account of the corneal reflection.

E. Taeger, l. c. p. 32, &c., says that *with the ophthalmoscope we do not see the walls of the retinal vessels*, but only the column of blood contained in them. The walls having the same degree of transparency as the retinal tissue, are, therefore, no more visible than the latter. The central light line is due to the reflection from the middle part of the blood-column; while the peripheral parts do not reflect the light back to the ophthalmoscope, but disperse it, and therefore appear dark red, constituting the apparent outlines of the vessels under the ophthalmoscope.

Tuberculosis of Choroid.—A Steffen (On Miliary Tuberculosis, and on Tuberculosis of Choroid—*Jahrb. d. Kinderh.*, II., p. 315, &c.) states that tubercles have always been found in the choroid where there was acute tuberculosis of the lungs, but they have been sometimes absent in miliary tuberculosis of the pia mater. Tubercles in the choroid have been found to be one of the earliest symptoms of miliary tuberculosis, but they may appear at any stage, and even as late as twenty-four hours before the fatal issue of this disease.

The Coating of the Tongue.—J. M. Da Costa, M.D., of Philadelphia (*Medical Diagnosis*), gives the subjoined variations of the coating of the tongue: In health the tongue has hardly a discernible lining; disease quickly gives it one. In inflammation of the respiratory textures, at the commencement of fevers, in disorders of large portions of the abdominal mucous tract, the epithelium accumulates, and the tongue has a loaded, whitish appearance. The coat is apt to be yellowish in disturbances of the liver, and of a brown or very dark hue when the blood is contaminated. But we must be very sure, in drawing our inferences, that the abnormal aspect be not due to the food partaken of, or to medicine. Its color is also modified by the character of the occupation. Thus, as Chambers asserts, there is a curious, smooth, orange-tinted coating on the tongue of tea-tasters. A local cause sometimes gives rise to a thick, opaque coat. For instance, decayed teeth may produce a yellow sheathing on one side. Affections of the fauces also occasion a deep-yellow hue.

Again, some persons, even in health, wake up every morning with their tongues covered at the back with a heavy coating, which wears off during the day.

Observations with the Thermometer.—In using the thermometer for clinical purposes, not less than two observations should be made daily, and every day at the same hour. Between seven and nine o'clock in the morning, and about seven o'clock in the evening, are regarded as the most appropriate periods. If only a single observation be taken, it is best done in the afternoon or evening.

Symptoms of Softening of the Brain.—Dr. Forbes Winslow (*Obscure Diseases of the Brain*) publishes instances in which circumscribed conditions of impaired sensation were the premonitory symptoms of softening of the brain; the defective feeling being manifested in some cases in the skin, in others in the tongue and fauces.

Optic Neuritis.—Dr. Hughlings Jackson, in cases of hemiplegia, has noticed this affection in greater frequency in connection with left-sided paralysis.

In lesions of the encephalon or meninges, Bouchut believes it is in general more marked in the eye corresponding to the hemisphere which is more seriously affected; Dr. Jackson, however, denies the existence of any relation between the side of the brain diseased, and the eye affected.

Epilepsy of the Retina.—Dr. Hughlings Jackson (*Royal Ophthalmic Hosp. Rep.*) has pointed out a peculiar condition of the retina, which he noticed in a patient with epileptiform convulsions, and which he calls *epilepsy of the retina*. The retina is entirely anæmic, a condition dependent, in all probability, upon a contraction of the retinal vessels, similar to that which occurs in the vessels of the brain during an epileptic fit.

Nitrobenzole.—This substance, which operates as a narcotic poison in vapor as well as in a liquid state, may, in the rapidly fatal cases, produce coma, which may be mistaken for the insensibility of apoplexy. But the poison leads quickly to death when coma has been induced, and is detected by its strong odor, resembling that of bitter almonds.—*Da Costa's Diagnosis.*

Temporary Blindness following an Attack of Intermittent Fever. — Dr. Dutzmann (*Wiener Med. Presse*, June 26) reports that a robust young man had been suffering with intermittens tertiana for a fortnight, when a new and more severe attack, complicated with violent clonic convulsions and entire insensibility, reduced the power of vision to feeble perception of light. On ophthalmoscopic examination nothing abnormal was discovered in the fundus of the eye. The patient took a strong dose of quinine, remained five hours in the same condition, then fell asleep, and when he awoke his sight was completely restored. Pigmentary embolism of the central retinal artery, with consequent transitory disturbance of vision, is suggested as a possible cause.

Herpes Ophthalmicus.—B. T. Vernon (*St. Bartholomew's Hosp. Rep.*, IV., 1868) speaks of cases of *Herpes Ophthalmicus*. All parts of the fifth nerve may be affected either isolated or in combination. Neuralgia may occur solely or together, with herpetic eruptions on the eye-ball and its surroundings (phlyctenular ophthalmia and herpes zoster frontalis); but also paralytic affections of some branches of the oculo-motor nerve are observed simultaneously, and this may be, perhaps, only a curious coincidence, but also in causative relation with the affection of the trophic or sensitive functions of the fifth pair.

Production of Bone from Medulla.—An interesting "provisional communication" appears in No. 24 of the *Centralblatt*, from the pen of M. Baikow, on the effects of transplantation of medulla. M. Baikow made two series of experiments. In one set, which were thirty-eight in number, the medulla from the femur or tibia of a dog was placed under the skin of the back of another dog; whilst in a second set, twenty-eight in number, the marrow was inserted beneath the skin of the back of the same individual. The first set of experiments all failed; bone was formed in none. In the second set fourteen cases succeeded—*i. e.*, bone was actually formed; whilst in the remaining six cases the changes that occurred in the early stages were followed. The remaining eight cases were unsuccessful. In the fourteen successful cases bony masses were found in various stages of development, from the earliest rudiments to complete formation, with Haversian canals, lamellæ, stellate lacunæ, and medullary cavities filled with medulla. Up to the present time, M. Baikow's experiments extend only to the seventy-sixth day. In one case, at the sixty-first day, not only was complete bone present, but fibro-cartilage. The results of examinations showed that the medulla, after transplantation, first passed into the condition of fibrous tissue, from which, by the proliferation of the cellular elements, bone or cartilage was developed. M. Baikow's results are in opposition to those of M. Ollier, but corroborate those of M. Goujon.—*Lancet.*

Influence of the Child in Parturition.—Dr. Villeneuve, after a lengthened inquiry, has published a long work on "The Proportion which exists between the Size of Children and their Vital Resistance in Normal Parturition." He has established, amongst other interesting facts, that of large children the number of boys is greater than that of girls; that the vital resistance of either boys or girls is in direct ratio to their development; that the deaths of mothers are the more rare in proportion as the children are larger, provided that the pelvis and the presentation are normal. Nothing would seem more reasonable to suppose, than that the larger the children are, the greater the obstacles to birth they meet with. This is Simpson's theory, and it is a satisfaction to be assured that the hypothesis is incorrect.—*Med. Press & Circular.*

Cæsarean Operation after the Death of the Mother; Child Saved.—Dr. Beckmann published in the *Berliner Klin. Woch.* of Dec. 20th, 1869, the case of a woman, aged twenty-five, who, in the eighth month of pregnancy, died of apoplexy. With the consent of the husband, the Cæsarean operation was performed within five minutes after the mother's death, and a male child, weighing hardly four pounds, extracted. It was seemingly dead, but by dint of persevering efforts at artificial respiration, life was recalled; and by means of breast-milk obtained from a neighbor, the boy did well, and has been frequently seen by Dr. Beckmann since March, 1867, when the operation was performed. A similar case has been published by Dr. Ploss in *Monatschr. für Geburt. und Frauenk.* of August, 1869.

Pain after Operations.—The narcotic effects of chloroform or ether destroy pain during operations, but many patients suffer severely after the narcotism has gone off. To prevent this, Professor Sédillot, of Strasburg, proposes to divide the tissues with the platinum wire brought to white heat by the galvanic current. This division should be effected very slowly, so as to prevent hemorrhage. The author states that no pain is felt on awaking; that the wounds heal extremely well, and that hospital complications do not occur.

Medical Items and News.

The Sewing Machine on the Health of Female Operators.—Dr. Decaisne (*l'Union Médicale*), after a careful investigation of 661 female operatives upon the sewing machine, proves that these operatives are not, as has been pretended, more subject than other working-women to metrorrhagia, peritonitis, miscarriage, and leucorrhœa; and that the cases which have been reported are evidently simple coincidences, and the result of a labor too severe for the woman's strength.

As regards the machines with the women as motive agent, those with isochronous pedals should be preferred to those with alternate pedals; in this way the operator is guarded from any excitation.

The Age at which Menstruation Commences.—Dr. Walter Rigden (*Lond. Obstet. Trans.*) gives the subjoined statistics obtained from females who were confined at *University College Hospital*. In 2,696 cases menstruation occurred for the first time:

At the age of	9	in 3	cases.	At the age of	18	in 150	cases.
" "	10	" 14	"	" "	19	" 76	"
" "	11	" 60	"	" "	20	" 29	"
" "	12	" 170	"	" "	21	" 7	"
" "	13	" 353	"	" "	22	" 3	"
" "	14	" 560	"	" "	23	" 2	"
" "	15	" 540	"	" "	24	" 0	"
" "	16	" 455	"	" "	25	" 0	"
" "	17	" 272	"	" "	26	" 2	"

It appears that it is most common at 14 years of age.

American Pharmaceutical Association.—This Association, after an interesting session of three days at Baltimore, Md., adjourned Sept. 15th. The next place of meeting is at St. Louis, on the second Tuesday of September, 1871. The following officers were chosen for the ensuing year. *President*, Richard H. Stabler, of Virginia; *First Vice-President*, Fleming G. Grieve, of Georgia; *Second Vice-President*, James G. Seede, of California; *Third Vice-President*, E. L. Massop, of Missouri; *Treasurer*, Charles A. Tufts, of New Hampshire; *Permanent Secretary*, John M. Maisch, of Pennsylvania.

The Oldest Man in New York State.—John Jackson, a farmer at Good Ground, N. Y., is claimed to be the oldest man in the State, being 115 years old. He witnessed many of the events which occurred during the revolutionary struggle. His wife died two years ago at the ripe age of 99 years. He has had 12 children.

A Course of Instruction in Ophthalmology and Otology.—A practical course of instruction on these subjects will be given at the Manhattan Eye and Ear Hospital, by Professors C. R. Agnew, M.D., and D. B. St. John Roosa, M.D.; and Drs. Edward G. Loring and Edward Curtis, during the months of October, November, and December, 1870. A similar course will be given during the months of February, March, and April, 1871.

Important Visitors to this Country.—It is announced that Prof. Tyndall, the physicist, Dr. Hooker, the renowned English botanist, and Prof. Huxley, the zoölogist, will visit the United States and Canada in 1872.

The Speculum.—Recamier enlarged his speculum in 1816, and introduced it to the world as a new and hitherto unknown mode of investigation, although it was well known and in constant use by the earliest practitioners of Egypt, Greece, and Rome.

Vital Statistics.—In New York, in 1810, one-half of all the persons who died were twenty-four years of age and upward; in 1820, half of the deaths were of persons only twenty years of age; in 1830, ten years of age equally divided the number of deaths; in 1840, half of all who died were only five years old; in 1850, at four years and under were half the deaths; in 1857, half the deaths were of children two years old.

In 1807, one-half of all the deaths in Philadelphia took place after the twenty-fourth year of age; in 1820, half the decedents were not yet twenty years old; in 1830, half the deaths were under sixteen years old; in 1850, half the decedents were under five years of age; and in 1856, one-half were under four years of age.

During the four years ending February 28th, 1870, there were reported to the Health Office in Cincinnati, 17,983 deaths. Of this number 8,659 were children under five years of age, or nearly one-half; and of these 80 per cent. were under two years of age.

Death of Russian Lady from Glanders.—We learn from the *Court Journal*, that the charming Madame Palesikoff was taken ill with glanders, in Berlin, and died in a few days. One of the horses belonging to her carriage touched her cheek and caused the trouble.

Placentitis.—Inflammation of the placenta is of rare occurrence, and was first mentioned by Guillemeau, in 1648, in his "Œuvres de Chirurgie." Brachet, in 1828, fully described the condition of hepatization, which he considered one of the stages of inflammation. It was recognized also by Désormeaux and Paul Dubois, and others down to our own times.

The Force of Uterine Contraction.—The extreme force of uterine contraction produces a pressure of 3.402 lbs. per square inch, which is equivalent to a pressure of 54.106 lbs. acting upon a circle of 4¼ inches in diameter, which is assumed as the average area of the pelvic canal.

The maximum force used to expel the fœtus, by both uterine and abdominal muscles combined, is estimated by Joulin, by forceps experiments made on the dead body, at 110.23 lbs., a result which is regarded by Dr. Duncan as too large. Dr. Duncan considers 80 lbs. as the maximum force ever employed in difficult cases. This would correspond with an hydrostatical pressure inside the uterus of 5.03 lbs. per square inch, which is greater than the uterine muscles, unaided, are capable of producing.—*Dub. Quarterly Journ. Med. Sciences.*

Vaccinal Syphilis.—Dr. W. B. Davis, in his interesting report to Ohio State Medical Society (*Cin. Lancet and Observer*), on "Is there danger of conveying other constitutional affections than vaccinia, by means of human vaccine lymph?" truthfully asserts that it is opposed by the experience of the greatest vaccinators and syphilographers. West, with an experience of 26,000 vaccinations; Marson, with 40,000; Sir W. Jenner, with 13,000; Seaton, with 50,000; Tompkins, with 50,000; Perkins, with 40,000; Loines, with 200,000; Clendenin, with 16,000, and many others which might be named, have never met with a case of vaccinal syphilis.

This opinion is supported by M. Guerin's terse assertion in the Paris Academy, that "Vaccination is not a port of entry for syphilis, but a means of exit."

He closes the report by quoting the declaration of Dr. Anstie: "Vaccinal syphilis is a bugbear and a phantom."

Paris.—According to the census of 1866, Paris had 1,825,274 inhabitants, and about 90,000 houses.

Wisconsin State Medical Society.—The Medical Society of the State of Wisconsin held its regular annual session in Milwaukee, on the 15th, 16th, and 17th of June, 1870, its President, Dr. S. Marks, of Milwaukee, presiding. The following officers were elected for the ensuing year: *President*—Dr. H. P. Strong, of Beloit. *First Vice-President*—Dr. Darius Mason, of Prairie du Chien; *Second Vice-President*—Dr. A. H. Van Nostrand, of Madison. *Secretary*—Dr. J. T. Reeve, of Appleton; *Corresponding Secretary*—Dr. R. D. McArthur, of Milwaukee. *Treasurer*—Dr. J. T. Reeve, of Appleton. Drs. J. Bartlett, H. Van Duzen, and L. S. Burrows were re-elected as *Censors*.

The Fœtus.—Dr. Palmer, of Wisconsin, alludes to a case in which a seven months' fœtus was found to be entirely destitute of any trace of osseous matter.

A Venerable Practitioner.—Dr. Theophilus Clark, of Tinmouth, Vermont, now 98 years old, and still hale and hearty, has practised his profession 66 years.

Berkshire Medical College, Mass. — This time-honored college was sold in August last to Dr. F. A. Paddock, of Pittsfield, Mass., for $8,150.

Injected Placentæ—Dr. Jas. T. Whittaker, Cin., Ohio (*Am. Journal of Obstetrics*), in his voluminous prize essay on "The Morbid Anatomy of the Placenta," states that the museum of Prof. Hyrtl, of Vienna, contains the most wonderful collection of injected placentæ—over 200 specimens.

City Hospital of Cincinnati.—At a late meeting of the Trustees of this Hospital, Dr. W. B. Davis proposed that the staff be requested to prepare an annual volume of reports. The proposition was approved and referred to the staff, who will issue the first volume in March, 1872.

The Epidemic of Small-Pox in Paris.—During the months of January, February, and March, 1870, eight hundred and ninety-six deaths from this disease occurred in Paris. It has been very destructive to children under three months of age, showing that vaccination ought always to be done as near birth as possible.

Absence of Uterus in Two Sisters.—A patient, aged 20, was lately in Guy's hospital, under the care of Dr. Phillips, in whom no trace of an uterus could be felt. She was of dark complexion, and was rather diminutive in stature. The external genitals were perfect; the pubes was covered with hair; and the mammary glands were well-developed. The vagina was represented by a short but dilatable canal ending as a *cul-de-sac*, in the mucous membrane of which there were three small apertures. By means of a careful pelvic examination, the uterus was found to be wanting, and no ovaries could be felt. She had been subject, since her marriage at seventeen, to pain in the loins, to sickness and headache; and these were increased in severity for a few days every month; but there had been no hemorrhage from the vagina, nor from any other part.

The patient stated that one of her sisters had never menstruated; and when the latter, aged 21, presented herself among the out-patients, it was found that a similar malformation existed. She also was married; was very like her sister in appearance, but taller; and, on examination, was found to have a short vagina, but, as far as could be ascertained, no trace of uterus or ovaries. —*British Medical Journal.*

Gonorrhœa.—According to Dr. Black, of Glasgow, married men have never been known to contract gonorrhœa from their wives.

New Preserving Fluid for Preparations.—M. Méhu, pharmacien of the Necker Hospital, states that for the last two years he has been experimenting with various antiputrescible fluids for the preservation of anatomical specimens, and has at length discovered one which answers excellently. This liquid only contains a small proportion of alcohol, and hence does not cause any considerable contraction of soft textures, which with him have chiefly been portions of the mucous membrane of the bladder, prostate, &c. It contains arsenious acid, which preserves them from decomposition, and the development of cryptogamic vegetation is prevented by the addition of a small quantity of crystallized carbolic acid. The formula is—Arsenious acid, 20 parts; crystallized carbolic acid, 10 parts; alcohol, 300 parts; distilled water, 700 parts. The preparation of this fluid has led him to notice the great solubility of arsenious acid in alcohol, which has not hitherto attracted attention.—*Lancet.*

Bromides in Epilepsy.—Benjamin Swan, M.D., of San Francisco, Cal. (*Am. Jour. Med. Sciences*), cites numbers of cases of epilepsy, all seeming to prove that a point is finally reached when the system becomes insensible to the action of bromide of potassium.

He believes the bromides to be the best remedies in epilepsy, but he has yet to hear of a case that was perfectly cured.

Rhinoderma.—Under the name of *Rhinoderma* Dr. C. Hilton Fagge, of London (*Guy's Hospl. Reports*), describes a disease, called by Devergie pityriasis pilaris, in which the skin is rendered rough like a rasp by the presence of horny accumulations in the mouths of the hair follicles.

Vomiting and Purging in Cholera Infantum.—B. M. Wible, M.D., of Louisville, Ky. (*Am. Practitioner*), uses the following formula when vomiting and purging are prominent symptoms: ℞. Tinct. opii, gtt. xvi; potas. bicarb. 3 ss; syrup. simplicis, 3 iij; aquæ menth. pip. 3 x. M.

Of this a teaspoonful is to be administered after each act of vomiting and purging. This prescription has answered his highest expectations.

A Dictionary of Science.—Moxon & Co., of London, will shortly issue a new Dictionary of Science, which is under the supervision of Mr. G. Farrer Rodwell.

A New Use for Glycerine.—Small quantities of glycerine are added to paper stock to give the paper greater flexibility, but especially to give copying paper the quality of taking up color readily.

A New Method of Purifying Gas.—Mr. Emerson McMillin, Superintendent of the Ironton Gas Works, Ironton, Ohio, finds that grind-stone dust, from factories where iron and steel tools are ground, entirely overcomes the inconvenience and disagreeabilities of the process of gas-purification. This dust is an intimate mixture of microscopic particles of silicic acid and iron. The grind-stone dust is sometimes mixed with clay, and dry lime, or loam; this serves to absorb the ammonia and the carbonic acid of the gas.

Statistics of Life.—The yearly mortality of the globe is 33,333,333 persons. This is at the rate of 91,554 per day, 3,730 per hour, 62 per minute. One-fourth of the population die at or before the age of seven years. One-half at or before 17 years. Among 10,000 persons, one arrives at the age of 100 years, one in 500 attains the age of 90, and one in 100 lives to the age of 60.

Original Lectures.

ANTIPHLOGISTIC TREATMENT IN DISEASES OF CHILDREN:

REMARKS BEFORE THE NEW YORK MEDICAL JOURNAL ASSOCIATION, APRIL 15 AND 22, AND MAY 27, 1870.

By A. JACOBI, M.D.,

CLINICAL PROFESSOR OF DISEASES OF CHILDREN, COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

Lecture III. Part II.

[Phonographically reported for the Record.]

I come now to speak of those antiphlogistics used in chronic inflammations—that is, in inflammations where the first change of an inflammatory character has passed by, and changes in tissue have taken place; the new-formed cells of the active stage have passed, for example, into fibres of connective tissue, or have undergone a degenerative change into pus. The remedies chiefly used in chronic inflammations are iodine and mercury.

IODINE.

The preparations of iodine most in favor for internal administration are the iodide of potassium, the iodide of sodium, and perhaps also the combination of iodine with iron. It has long been known, from clinical experience, that iodine has a good effect in inflammatory diseases of the glandular tissue. But it is necessary to distinguish between the different kinds of glandular inflammation, and I shall speak of this the more at length because the subject is so important in practice among children.

Inflammatory enlargement of a lymphatic gland takes place either from increase of the number of glandular cells, that is, hypertrophy of the gland proper, or from increase of its connective-tissue cells and fibres. The results of these two kinds of enlargement are very different, and so, too, is the frequency of their occurrence. Increase of the glandular structure proper, without complication, is extremely rare, while increase of the connective tissue alone is very common, and gives rise to a large number of chronic glandular diseases. The process is this. We have, say, a local inflammation of some of the glands of the neck from eczema of the scalp, or inflammation of some of the mesenteric glands from diarrhœa, that is, congestion and catarrh of the intestine. Hyperplasia of the connective tissue of the gland takes place, resulting in compression, and finally in obliteration, of its lymphatic ducts, and even of its blood-vessels. Cut open such a gland, and you find it unusually white in color, and very dense in structure. Clinically it is found no longer to perform its functions; it is useless in effecting the further development of the lymph-corpuscles. Indeed, a gland which has undergone this kind of hypertrophy is worse than useless; it is in the way, by compressing the parts in its neighborhood. Hypertrophy of this kind will hardly yield to medical treatment. The great majority of the cases of enlarged lymphatic glands above the region of the neck are of this character. Thus the deep-seated facial glands under the lower jaw, after having been long enlarged, will rarely be found amenable to any treatment but the knife. So, too, enlarged tonsils will seldom get well under iodine treatment; and if the enlargement be of long standing it is well known of how little service are all our caustic applications, though, if recent, the iodide of potassium or sodium, or the tincture of iodine, may do some good. There is no communication between the blood-vessels of the skin and the few blood-vessels left to supply the gland after chronic induration; and as we expect the iodine to reduce the induration, if at all, by its action as a local irritant over the affected part, we should not look for much good, in such cases, from painting the skin over the gland. The iodide of potassium given internally (or the iodide of sodium, which I prefer as being more digestible) may have more effect, because it enters the general circulation, and so enters the gland with the blood. It will act with benefit before the connective-tissue fibres have become fully developed, but not afterwards. The same thing may be said of the treatment of cirrhosis of the liver, interstitial inflammation of the lungs, etc., where we have the same kind of new formation. Fully developed connective-tissue fibres are not influenced by iodine.

A mode of applying iodine which I have often resorted to, especially in glandular affections about the neck, is not, I think, in common use. If we can apply our remedy directly to the lymphatic absorbents going to the affected gland, we certainly do better than if we exhibit it internally and run the risk of its being lost. Now, the lymphatic glands of the neck can be so reached. For example, most of the lymphatic glands in the neighborhood of the parotid and of the arch of the inferior maxilla, the majority of which are covered by the sterno-cleido-mastoid muscle, can be reached through their absorbent vessels situated in the lower portion of the nose and in the cavity of the mouth. By applying, according to E. Schönfeld, the iodide of potassium locally, either in powder or in solution; by painting the tonsils and the pharynx with tincture of iodide; by now and then using a mouth-wash of iodide of potassium, especially for glands situated near the median line—we can get the discutient action of iodine upon these glands much better than in any other way. I am confident that I have thus obtained good results where I had long given up other treatment in disgust.

The use of tincture of iodine as a local derivative is too familiar to be spoken of. I believe that in recent cases of glandular swelling it will do good in this way, simply as a derivant, and not that anything is absorbed through the skin, for if there be any absorption at first, there will not be after a few applications.

The salts of sodium being all more digestible than those of potassium, I prefer the iodide of sodium to that of potassium. It requires a larger dose, however—about double. Where I should give a baby four or five grains of iodide of potassium in the day, I should give eight or ten of iodide of sodium. As to salves, from those usually found made up I have seen no effect; and I think iodine is never found in the urine after their inunction. A better vehicle to insure the absorption of iodine by the skin, where the stomach refuses it, is glycerine. It is a positive fact that iodine will be found in the urine within twelve hours after the first embrocation of a solution of iodide of potassium in glycerine. I usually dissolve about half an ounce, or less, of the iodide in an ounce of glycerine.

MERCURY.

Mercury is a drug which we all know is used a great deal as an antiphlogistic, in acute as well as in chronic diseases. I have not the slightest doubt that it is used much more than it ought to be, and especially in diseases of children.

It has been said that it is much better tolerated by infants than by adults, and this has been taken as a reason for dosing them with it. It has been said that

infants will not be salivated by mercury. True enough, and for the best of reasons. Infants, up to the end of their third month, have, as it were, no salivary glands —at least no genuine salivary secretion. This much has been proved by the researches of Prof. Ritter of Prague. (There is an exceptional case on record of secretion of saliva at the seventh week.) And if these glands are thus rudimentary, we should not expect to find even a morbid secretion excited by agents which would affect them powerfully when more developed. But, it is argued, even older children are not salivated so readily as adults. This is chiefly because they have fewer teeth; so the mercury has less chance to be retained in the mouth till it is absorbed, to be thrown again into the mouth with the saliva, and then reabsorbed, thus producing the maximum local effect, as in the salivation of adults.

The general effect upon the system, however, remains the same; and it is this general effect which is the very worst in any inflammatory disease, especially of children. Mercury is said to have an antiplastic effect, to diminish the fibrine in the blood. But inflammation means now a very different thing from what it did formerly. We know that when the blood is thinner than normal, inflammatory effusion and exudation, like effusion generally, will take place more readily. So, whatever we do to change the blood, except to improve it, is, in my opinion, injurious, no matter what the disease we have to deal with. If an inflammatory disease has a tendency to effusion, and if, moreover, it has a tendency to debilitate the system by impoverishing the blood, we should avoid every remedy which will conduce to this impoverishment, as mercury will certainly do.

Again, the principal effect of mercury is not one rapidly developed; it requires a great number of small doses to obtain it within a day or two. But in the inflammatory diseases of children the effect we seek must be a very speedy one; unless we can get it within a day or two we may as well give up the attempt, for before that time effusion would be established; the inflammatory action of exudation would be completed, and then the regular process of disintegration and absorption must take place—a process better carried on by good normal blood than by blood impoverished by debilitating drugs. Clinical experience testifies that whatever we do to weaken the blood interferes with rapid convalescence after an inflammatory disease. I have myself said that, in former years, I was often under the impression that I cured the disease and yet lost my patient. This was when I used depletion now and then, and mercury on a large scale.

I believe that is all I have a right to say concerning mercury as an antiphlogistic. Of my own habit I may simply remark, that although I see a large number of diseases of children in private and dispensary practice, I am seldom under the necessity of using it. Perhaps I am a little pedantic in the matter. I have made it a point to teach and to prove that mercury is given too frequently; that it is apt to do harm; and that the effects we seek from it can be gained as well by other remedies. Therefore, in diarrhœa, etc., where mercurial preparations are so often used, I have made it a rule to give them as rarely as possible—indeed, I may say, never. I have forbidden the use of calomel and its cognates to all my dispensary and clinic patients; there is not one of them that has had a grain of calomel for ever-so-many years. I make this statement, pedantic though it seem, to show that we can get along without mercury in most of the cases where it is usually given. There is but one class of affections in which I would and do employ it—that in which a new formation is of a heterogeneous character, as, for instance, in syphilis. I seldom use anything else than calomel in the syphilis of the new-born; almost never do I find it called for in any other disease.

ELECTRICITY.

Of one other remedy, lately brought into vogue, I may say a few words. Electricity is to be accounted among the antiphlogistics, especially in chronic, but also in acute, cases. The constant current, in particular, may be used for the direct purpose of contracting the blood-vessels through its action on the sympathetic nerve. Applied to the sympathetic in the neck, it has been so employed in inflammatory or congestive affections of the brain. I have myself no experience in that matter. Benedict speaks of having used it in cases of so-called tubercular meningitis, especially some in which he could watch the progress of the disease with the ophthalmoscope. At the same time I must add that he, as well as every other electrician, denies the assertion that the condition of the circulation in the retina and choroid can be taken as a positive index of that in the brain. The blood-vessels of the retina perforate the sclerotic, a dense and hard membrane. In case of active hyperæmia, which may be local or extensive, and consecutive swelling, the return of the blood is impeded. The results are stagnation, dilatation of vessels, proliferation of connective tissue; finally *diminished* circulation, and atrophy of vessels and nerve tissue. Thus the very same condition of the brain may give rise to different ophthalmoscopic results. The enthusiasm about the ophthalmoscopic examination of the retina, and its importance in the diagnosis of encephalic inflammation, dates from Bouchut, who, after he had seen a number of cases, published a very big book and a large atlas, to show that he could discover tubercular meningitis in its incipient stage. It is not strange that such an alleged discovery, concerning a disease so fatal, should have excited much enthusiasm, and stimulated the hope that a readier diagnosis might lead to better means of treatment. But, though Bouchut has merits of his own, I think he is here at fault. We cannot detect cerebral hyperæmia in this way. Yet the ophthalmoscope has done something for diagnosis. Miliary tuberculosis of the choroid has, by its means, been discovered in, now, perhaps two dozen cases, sometimes even before brain symptoms set in, so as to be conclusive of tuberculosis of the brain; but it was done by the discovery of the tubercles themselves in the retina. Thus far, however, no improvement in treatment has resulted. I make these remarks simply to show how easily enthusiasm, while capable of opening new fields of research, and conquering new facts, may lead sound judgment astray. We have not succeeded yet in reading the condition of the brain from the open leaf of the retina.

So much for the galvanic current in its influence on acute inflammations. It has, I think, a better influence in chronic cases. Its chemical action is well known. When the constant current is passed through water, it will decompose it. Similarly, solutions of alkaline salts are decomposed; iodide of potassium, for example, will show the potassium collected at the negative pole. Now if, by means of gilded needles, etc., the galvanic current is passed through any tissue, both the salts and the water of the tissue will be decomposed; and when its salts and its water are broken up, the tissue itself is broken up. Many cases have shown that new-formed morbid growths may be broken up in this way; but not only these, healthy tissue will yield as well. Althaus has proved that bone, teeth, and other tissues are decomposed with a facility proportionate to the amount of water they contain. I have found, in a

number of instances, that the electric current would produce absorption where iodide of potassium, etc., had no effect. Thus in a case of indurated mastitis of the newly born. At the same time I must say that in a number of cases it has proved unsuccessful, in all probability from an as yet insufficient knowledge of its powers, or from their improper application.

In the application of the current to cancerous tumors, etc., I have but little experience; enough, however, to show me that I cannot concur in the views of those who say that the current, whether applied by the sponge-electrodes or by gilt needles introduced into the tumor, will never produce suppuration and sloughing. That it will sometimes occasion these I know, for I have seen it. But I have seen a few instances where tumors undoubtedly scirrhous have become reduced in size under this treatment. A case of which I am now thinking is that of a woman with scirrhus of the left mamma, upon whom I have operated now four times. The first operation was seven years ago; the other three were simply to remove portions of the cicatrix, the last of them for the purpose of proving, before the Pathological Society, that the case was one of scirrhus. That case has been treated by the galvanic battery, and in every instance, after a few applications, the swellings would diminish in size; yet in that case, even when the needles were introduced, I have seen suppuration occur.

It does not belong to me here to speak of the cases of stricture, affections of the uterus, etc., which have been treated by the galvanic current. I mention them merely because so much has lately been written on the electrolytic treatment; and because I have seen many chronic inflammatory swellings go down under the influence of galvanism, in part, doubtless, from its electrolytic action, and in part from the local irritation.

Still it is true, also, that tumors will give way under simple faradization; and it is only justice to give credit to a writer who published two little books on the subject eighteen years ago, but is now almost forgotten by electro-medical authors, even by our own Morgan, whose knowledge of literature was astonishing. I refer to Hassenstein, who gives a number of instances in which swellings were diminished by the induced current, among them a bubo.

I may be pardoned for dwelling so long upon this subject, because, although I believe the enthusiasm concerning it has gone a little too far, I am yet convinced that electricity, and especially the constant current, will have a great effect upon many chronic diseases, and may possibly prove very valuable in the treatment of brain affections, chiefly, perhaps, by modifying the circulation.

DIET.

I have omitted to speak of diet. If I were to make any remark upon it, it would be to endorse what Dr. Flint said so admirably, in a paper read before the County Society, and since printed in the *New York Journal*.* I said just now that convalescence was often protracted by the effect of debilitating drugs; on the other hand, if there is anything that will bring about speedy recovery it is good feeding. Dr. Flint makes one remark, however, with which I cannot agree, and this is the only exception I would take to his paper. He says, if I am not mistaken, that if we give food in excess of the demands of the system, it does no harm, for the surplus is easily eliminated. But I think that we may feed too much; and that, especially in acute inflammatory troubles, we may thus injure the patient. Children with an acute inflammation ought not to eat much, but they have a strong desire for drink; by eating they will increase the amount of waste matter that is to be eliminated before health can be restored, and so will feed the fever instead of themselves. It is very important to forbid the nursing of babies too frequently in inflammatory and ephemeral fever. In pneumonia, for instance, we commonly find the infant is not given enough water, but whenever it wants to drink is fed from the breast; and thus is increased the gastric catarrh which we always have in fever. This indiscriminate nursing, because the baby is "thirsty," must be firmly prohibited, and plenty of water allowed.

One remark further. At a certain period of the fever, when the temperature goes down, and we have a right to expect that absorption will take place, we should commence to feed, no matter whether the child shows appetite or not. When the stomach has been lying idle for some time, there is a great deal of waste material, mucus, etc., coating its surface, with a deficiency of gastric juice and pepsin, even when food is introduced. We should introduce food, then, to exercise the stomach, and assist it in throwing off the mucus and old epithelium. The French have a proverb that appetite comes during eating; and we find that when children, at the stage of fever I have described, have been fed once or twice, they recover their appetite.

* *N. Y. Med. Jour.*, Feb. 8, 1868. See report in MED. RECORD, vol. iii, p. 18—REPORTER.

A LECTURE
ON
THE MENTAL STATE OF EPILEPTICS,
AND
ITS MEDICO-LEGAL RELATIONS.

BY MEREDITH CLYMER, M.D.

PART I.

BEFORE finishing the subject of epilepsy, let me ask your attention to a brief inquiry into the mental state of those afflicted with it. We will endeavor to ascertain by clinical analysis the frequency, kind, and degree of psychical troubles which so commonly attend this malady. I believe that in every case of epilepsy there is some modification of mental tone, but it may be of a kind and degree not to affect either the moral or legal responsibility of the individual. We may have the whole gamut of insanity sounded from irascibility and capriciousness of thought, feeling, and conduct, to the most terrible explosions of maniacal fury. Esquirol speaks of the intellectual faculties of the epileptic becoming more and more degraded, and of the tendency to moral perversion. Of 339 epileptics, he found 269, or four-fifths, suffering with some degree of insanity, leaving only one-fifth in the enjoyment of their reason, and he remarks, "What sort of reason?" Musset says:—The senses become obtuse, the intellect is weakened, and memory lost, and there is incapability of sustained thought and work, dementia, in the majority of cases, being the usual ending. J. P. Falret observes (*Des Maladies Mentales*, Paris, 1864, p. 339):—"It is certain that very many cases of epilepsy are accompanied by some disorder of the intellect which has a decided analogy to that met with in a large number of the chronic diseases of the brain, and of which the upshot is dementia or idiotism. This trouble is as natural a consequence of the principal disease as those partial par-

alyses so frequent after epileptic fits, and should not be separated from the disease upon which it depends. On the one hand we have cases of mental derangement, accompanied by vertigo or even true epileptic attacks, and which are chiefly characterized by their short duration, intermittent type, outrageous exhibitions of passion, and by hebetude and want of memory after the paroxysms; cases so distinctive in their character as to merit the name of epileptic insanity. Doubtless these distinctions, which seem to us so clear in principle, are often difficult to establish in practice; but is not this rather owing to the present imperfectness of the diagnosis of cerebral diseases?" Trousseau says: "You are well aware that this fatal influence of epilepsy on the intellectual faculties, of which dementia, idiocy, and general paralysis are the ultimate expression, is a well-known fact, which has been long ago pointed out. If there have been epileptics who, in spite of more or less frequent attacks, have retained, to the end of even a pretty long career, not only the fulness of their reason, but also the full force of their intellect, and like those men of genius, whose names history has handed down to us, have preserved that superior intelligence which enabled them to rise above the ordinary level of their fellow-men, instances of this kind are too exceptional to invalidate in the least the general law. In the great majority of cases, although in the beginning, and when the attacks are infrequent, the patients are in the full possession of all their faculties, although a marvellous aptitude for conceiving things quickly, or viewing them under their most brilliant and poetical, aspects may distinguish some of them, as Dr. Morel has remarked; yet in proportion as the fits recur and increase in frequency, in proportion as the disease progresses, the faculties fail, are impaired, become gradually extinct, and insanity follows."—(*Clinical Medicine*, Bazire's translation, vol. i., p. 66.) On the other hand, Dr. J. Russell Reynolds states, as the result of his inquiry into the mental condition of epileptics, that there is no necessary relation between any form and degree of mental deterioration and epilepsy. Still his statistics show only about one-third of his epileptic cases in which there was perfect (*i.e.*, average) mental integrity; in a little less than two-thirds there was some intellectual failure, but this existed in a high degree in only a very small proportion. Women he found to suffer more frequently and more severely than men, and the commonest form of failure to be that of defective memory, this faculty being lessened especially in regard to recent and trifling events (*On Epilepsy*). This statement, accurate, no doubt, so far as Dr. Reynolds's cases are concerned, is certainly at variance not only with the general belief, but with the experience of almost every other observer, and with what we might naturally expect to happen. Still, as the opinion of a very eminent, trustworthy, and conscientious physician, and one of large knowledge of this malady, I have thought it right to mention it to you. His analyses of the conditions which determine mental failure in the epileptic are valuable and instructive, and I will give you a brief of them:—

Hereditary taint is without influence. The age at which epilepsy begins has a certain degree of influence, and to this effect—when the disease appears late in life, it is more commonly connected with mental failure, and the chances of mental failure are less than when the first attacks happen before puberty. Late, rather than early, epilepsy then predisposes to intellectual deterioration, and this, whether we divide the cases at the tenth, sixteenth, or twentieth years; and whether we consider the two sexes together, or each separately. The duration of the disease is, *per se*, without influence upon the mental condition of the intellect. The amount of mental deterioration is not in direct, but in inverse, proportion to that of muscular disturbance, as shown by the presence of tremor or spasm, either clonic or tonic. The state of the general health does not account for that of the mind; the former may be good, and the latter bad, and *vice versâ;* and contrary to what would be expected, such relation is more usual than the co-existence of marked failure or integrity in both directions. The number of attacks does not determine either the degree, or the existence of intellectual change; but frequency of recurrence of seizures is, however, associated with it, but in such manner as to show that it is not the sole condition of such result, and that it is not even a necessary condition. The severity of the convulsive paroxysm is without apparent influence, when it is judged of by the duration of the following coma. The form of attack appears to have considerable influence. Neither seizures of *le haut mal*, nor those of *le petit mal*, necessarily induce this change; but the mental deterioration of epileptics is much more clearly associated with the minor than the severer seizures. The nature of the exciting cause—that is, whether psychical or material—seems to be without influence in the production of mental change.

I have already had occasion to mention the uneasy, depressed, irritable state that so often immediately precedes the fit, and the disturbance both of the affective and intellectual faculties which is frequently manifested directly after, and may persist during a large part, or the whole, of the interval between the attacks.

The testimony of nearly all observers is, therefore, that epilepsy, whether in the lesser or more classical form, exercises a pernicious influence on the psychical faculties of its victims. A troubled brain is, I believe, the rule with epileptics; they dwell on the border land of insanity, into which they are liable at any moment to make an excursion, and where they may be condemned to dwell. That the existence of the malady is not incompatible with extraordinary intellectual power I do not deny; I have seen instances myself, and there are several familiar stock cases cited by authors, the most remarkable amongst them being those of Cæsar, Mahomet, and Napoleon Bonaparte. The imperial biographer of the great Roman denies that the two nervous attacks which he had, one at Cordova, and the other at Thapsus, were fits of genuine falling sickness. There is no real proof that Napoleon was subject to epilepsy, whilst there is much to discredit it. But where genius and epilepsy have indisputably coexisted, there have been nearly always, so far as my knowledge and experience go, a nervous constitution, singularities of thought and ways, which not unfrequently have sooner or later developed into some form of decided mental disorder. Children, who in after-life become epileptic, are often remarkable examples of precocious cleverness; they are bright, quick, full of imagination, and have astonishing memories, but are apt to be shy, tetchy, and quick in quarrel, and are almost always liable to sudden gusts of temper. These unnatural gifts, too, are not lasting; the promise of the child is not fulfilled; he becomes stupid, morose, fearful, and blustering. The cerebral excitement is the evidence of the morbid germ which later is to be developed.

In the epileptic the affective faculties chiefly suffer. The disposition is apt to be moody, fitful, suspicious, and quarrelsome. Offence is readily taken; there is a fancy to tease and annoy, and to be troublesome; and a dread of insult or injury. The moral qualities are perverted, and the sense of propriety, decency, and duty obscured or lost. The char-

acter may change—the temperate become addicted to drink and other excesses; those who have been especial favorites or greatly loved objects of hate or mistrust. Some fancied injury or slight brings on a burst of temper, with violent gesticulation and threatening language, which generally ends in words.

An epileptic is often of very variable mood, and his changes of humor are frequent and rapid. He who a few hours before was wayward, cross-grained, spiteful, and rebellious, may be engaging, docile, courteous, or even cringing. One who has been left a short time before cheerful, gay, hopeful of the future, and full of love and kindness, may be seen

—— sitting on the ground
Musing full sadly in his sullein mind,

deploring his sad fate to be condemned as a man forbid to banishment from friends and family, and inveighing in all the bitterness of his heart against his immedicable ill.

At times the same sort of mental exaltation may be met with which characterizes the general paralysis of the insane. There is unnatural hilarity, absurd estimate of executive ability, and exhaustless projects of impossible execution.

A large number of epileptics fall into dementia.

The psychical phenomena to which I wish at this time particularly to direct your attention are, though perhaps of the same kind, are more distinctive in their character, and more marked in their manifestations, and are sometimes the only objective indication of the disorder. They may not only precede or follow a regular fit, but they may take its place, and constitute actually a masked epilepsy. These points in the clinical history of epilepsy, of so much importance and interest to the psychologist and medical jurist, have not received the attention from the majority of writers on this malady that they merit, though a few have made them the object of particular study; but their essays are, for the most part, either not generally known, or of difficult access. I will endeavor to give you the results of these investigations, and shall begin by mentioning some clinical facts illustrative of the psychical derangements most often met with amongst epileptics, and more particularly of the rarer and least understood forms.

These psychical perturbations are characterized by sudden and irresistible impulses often of the most dangerous kind, accompanied with homicidal or suicidal tendency. Esquirol has called it *automatic fury*, and this term is strikingly indicative of the kind of mental derangement. Maudsley well remarks: It is not so clearly understood that the mental derangement so occurring may have the form of profound moral disturbance with homicidal propensity without manifest intellectual derangement. This writer points out the frequency of these precursory phenomena in children who subsequently become epileptic. He says, children three or four years old are sometimes seized with sudden fits of shrieking, desperate stubbornness, or furious rage, in which they bite, tear, and destroy whatever they can lay hold on; these may occur periodically, and may either pass in the course of a few months into developed epilepsy, or alternate with epileptiform attacks, representing a vicarious epilepsy.

Marc mentions a case of vicarious epilepsy in the adult: a peasant, aged twenty-seven, a victim to epilepsy since he was eight years old, had at twenty-five, when the convulsive fits ceased, an irresistible homicidal impulse. Often for days before, when he felt the warnings of an attack, which were weariness, depression, insomnia, and slight convulsive movements of the limbs, he begged to be confined that he might be hindered from committing a crime. "When the feeling comes upon me," he said, "I must kill some one, if only a child."

A shoemaker subject to severe epileptic fits, frequently followed by temporary attacks of fury, but who in the intervals was good-humored and docile, one day met the superintendent of the asylum, of whom he was very fond, and instantly stabbed him to the heart. He had not had a fit for three weeks, but the night after the deed he was seized with one, and others followed during some days.

Morel mentions the case of a boy at a boarding-school, who was suddenly attacked during the night without apparent cause; he rushed wildly up and down the hall of the dormitory, shouting and gibbering loudly, and seized one of his fellow-pupils who was trying to quiet him and attempted to strangle him. After some difficulty he was secured and put to bed, when he had an epileptic fit. The next morning he recollected nothing that had happened, but complained of feeling weary and exhausted.

Dr. Ludwig Meyer tells of a boy thirteen years old, who was subject to periodical attacks of fury, followed by epileptic convulsions generally but not always, the fits of furious maniacal excitement sometimes happening without the ordinary epileptic phenomena.

A Belgian named Rœgiers, 30 years of age, had been for seven years subject to epilepsy, the consequence of sudden fright. The fits after a while were accompanied with severe attacks of madness, so that every body was afraid of him; woe to the one who opposed him whilst he was suffering from the malaise preceding the onset. He had a foreknowledge of the attacks, and warned those about him. The fit over, he became, as he was naturally, calm and gentle, without any recollection of what had happened. The access took place commonly during the night, and was betokened by his face becoming very animated and congested; his eyes were brilliant and seemed to start from their sockets, his sight was dim, and everything around him confused; the veins of the neck were swollen, and up to the moment that the attack was fully developed, he struggled like a maniac, and was disposed to commit any violent act if not restrained. Rœgiers had had a quarrel with another man, in consequence of which he had been sent for some months to prison. On quitting the prison he assured B*** that he had no grudge against him, as he was not responsible for the act of the court. Some time after Rœgiers was seen quietly sharpening a knife on a grind-stone for over two hours, exclaiming from time to time, "I'll have your head." He left his house in broad day-light, knife in hand, and ran to the house of B., who lived in a populous quarter, and entered boldly. B. seeing R. come in armed with a knife, attempted to escape, but was pursued by R., who struck a blow at B.'s sister, while attempting to shelter her brother; reaching the latter, he threw himself on him like a tiger, and inflicted a terrible gash in his throat, thrusting in his fingers to enlarge the wound. The terrified bystanders refused any assistance until R. fell exhausted. Tried at the Brabant Assizes, he was condemned to death. He had no recollection of the horrid deed he had perpetrated, answering all the questions of the judge: "since you say so, I suppose it is so, but I know nothing of it." Subsequently his sentence was commuted to the galleys for life and one hour in the pillory. Whilst he was undergoing the latter part of his sentence he was seized with a terrific attack of convulsions.

Morel places the following case under the head of epileptic mania, though neither vertigo nor convulsions were at any time present, before or after:—

N***, when twelve years old, was violent and uncontrollable; on the slightest rebuke by his parents or teachers he would lie down and roll on the ground as if he had convulsions, seizing and biting furiously any object that was near, the attack of rage going off in a flood of tears. His temper was fitful, and he would pass from gayety to sadness and the reverse without reason. He was very combative, and constantly quarrelling with his companions. Married early and a father, his disposition did not improve, and terrific outbreaks of temper followed the most trifling causes. These were attributed to excess in spirituous liquors, but his wife remarked that he "would bounce with rage whether he had drunk anything or not." One day, after some harmless remark had been made to him, he rose, apparently perfectly calm, went to the stable, seized a knife, and ripped open the belly of one of the horses. At another time, while at the dinner table, utterly unprovoked, he suddenly broke a tumbler, ground it in small bits, and threw it into his soup, which he swallowed. It was sometimes several hours after such acts that the rage-fit exploded in terrible yells and horrible menaces against the members of his family. Once he precipitated himself on one of his children, helpless in bed with Pott's disease, and would have strangled it had not some one interfered. This man made three attempts at suicide, and after one of them his first act on coming to was to abuse those who had saved him, blaming them for all his sufferings.

Another, a female, forty-eight years old, had an attack eighteen months before, accompanied by violent acts and threatening language; after this interval there was another precisely similar. Both were of short duration. For some time after admission, Dr. Morel was undecided as to the state of this patient's mind, she was so calm, rational, and industrious. There was not the slightest evidence of any mental disturbance. One day, however, she suddenly began to use threatening language, and very soon followed the menace by an overt act of violence, and it became necessary to shut her up. So violent was this attack of rage, that she was no longer recognizable, and it was impossible to believe that it was the same woman who only the evening before was considered a model of gentleness and good behavior. After some days she resumed her duties with her usual willingness and good humor. Other attacks followed; the fits became more frequent; and after awhile her character began to change, and during the lucid intervals she was apt to be irritable, and easily provoked.

Another case of furious periodical mania may be cited: When admitted into Morel's asylum the woman was thirty-one years old; three years before she had had a fall on the head, since which time she had been subject to violent anger-fits, brought on by the slightest opposition or annoyance, and often without any cause. She would suddenly rise from the table, and pitch a plate, or anything she could lay hold of, at the head of some one in the room. These attacks were of short duration, rarely lasting more than one or two days. Since her admission the outbursts continued from time to time, without provocation. She is represented as having the peculiar shy character of epileptics—being abstracted, morose, apparently timid, and of weak intellect.

I will relate one more case, and a very instructive one it is, and I shall have occasion to again refer to it when I come to speak of the criminal responsibility of epileptics. It is that of Bisgrove, who had a narrow escape from the gallows, and which made a good deal of stir in England about two years ago. Bisgrove was an illegitimate child, badly cared for, and had been from youth of weak health and intellect. For several years he suffered from frequent epileptic fits, in consequence of which and his inability to take care of of himself, he had been discharged from the colliery where he worked. In the intervals of his fits he was good-natured and amiable, and liked by his companions, but after one of them he was dangerous, seizing upon anything which might be at hand, and ready to attack those who were near. Hoping that a sea-voyage might do him good, he shipped, but returned after a few months, unimproved. Bisgrove had the heavy, lost look, so common in confirmed epilepsy. Such was his condition when, one evening, after drinking a little, he saw a man unknown to him lying asleep in a field; he took up a big stone which was by, and dashed out the sleeper's brains. Having done this, he lay down by the side of his victim and went to sleep. When he woke, he was taken into custody, tried, defended (?) by counsel appointed at the last moment by the court, who said not one word of this creature's epilepsy, or of his previous history, and was condemned on circumstantial evidence, along with an innocent man, who gave a perfectly true account of his doings and whereabouts on the night of the murder, but was not believed. Soon after sentence, he made a confession of the crime, exculpating his supposed accomplice from any knowledge or part in it. A clergyman, struck with the strange character of the murder, made inquiries about the culprit's former life, found out that he was an epileptic, and had the proper representations made to the Home Secretary; a medico-judicial inquiry into the state of the prisoner's mind brought out the fact, a reprieve granted, and he was sent to Broadmoor Asylum. I shall presently have more to say about this monstrous error of justice.

PRACTICAL SUGGESTIONS

FOR THE

TREATMENT OF LACHRYMAL DISEASES.

BEING REMARKS MADE BEFORE THE N. Y. ACADEMY OF MEDICINE, SEPT. 15, 1870.

By C. R. AGNEW, M.D.,

NEW YORK.

The title of my discourse will relieve me from the necessity of attempting a systematic dissertation upon the general subject of lachrymal diseases, and show that my present purpose is to lay before you a few practical suggestions in such a manner as to make them, if possible, the property of all my hearers. The most common form in which incipient lachrymal disease presents itself to the practitioner is that of the weeping eye, as it is familiarly called, and a few words upon its pathology and treatment will naturally introduce our theme. It is observed that the patient begins to be annoyed by having his lachrymal secretion increased so as to overflow the edge of the lower lid, and trickle down the cheek, rendering the use of the handkerchief frequent.

This abnormity may follow an advancing catarrh of the eyes or nostrils, or come on gradually without any appreciable cause. When this state of stillicidium or overflow of tear occurs, the practitioner should examine with great care the puncta, to see whether they are of normal shape and in the proper relations to the surface of the eyeball. Abnormities in the inferior punctum are to be met with more frequently than in the superior, and their influence in producing stillici-

dium is much more marked. Commonly, one or more of the following lesions may be observed:

1. Eversion of punctum.
2. Obstruction or malformation of punctum.
3. Closure of punctum.
4. Inversion of punctum.

Any condition which alters either the shape or position of the inferior punctum is likely to cause stillicidium. For slight degrees of eversion the simple slitting up of the corresponding canaliculus is usually sufficient, care being taken to carry the cut down to the bottom of the vertical portion of the canal, that an opening may be made beneath the level of the secretion accumulating in the lacus lachrymarum. This simple procedure will do for slight degrees of eversion, such as we observe in the old subject, or in cases of chronic palpebral conjunctivitis, and all cases in which there is not such a loss of substance in the corresponding lid as to render a blepharoplastic operation necessary. It may be demanded also as one of the steps in a radical operation for eversion. The obstruction spoken of as forming one of the causes of stillicidium may be due to inflammatory or cicatricial changes in the edge of the lid, or in the lining of the canaliculus; but whatever its special cause, the only treatment indicated in the beginning is a free slitting of the canaliculus. If there be inflammatory changes in the canal lining they will require subsequent attention. We occasionally find obstruction due to a foreign body in the canaliculus. In two cases, I have removed from the inferior canal dacryolithes, which had produced stillicidium, and become by slow accretion of the size of a barley grain.

When the inferior punctum is wanting and stillicidium exists, we can usually find and open the corresponding canal by the following simple procedure:—Standing behind the patient, and holding his head in such a manner as to give it firm support, the lower lid should be slightly everted, and its edge made tense by being drawn in the direction of the temple. Then, with a pair of scissors of medium size, so made as to cut at their very points, you should snip the edge of the eyelid perpendicularly to its conjunctival border, to the depth of about a line and a half, cutting across the known course of the canaliculus. The canal once entered, the usual slit should be made throughout its entire length, and treated afterwards, to prevent closing, by running a probe daily between the raw edges until they have healed without uniting.

When the stillicidium is due to inversion, some operation to correct the in-turning tarsal edge is usually necessary as a preliminary step, and before any interference with the punctum. I would recommend that in all instances in which Bowman's operation, or slitting of the canaliculus is needed, the narrow straight knife of Weber be used, and so carried forward in the act of cutting as to make the line of incision through the back wall of the canal rather than upwards upon the tarsal edge; by so doing, your wound is not only hid from view, but placed in contact with the gathering lachrymal secretion.

We should not be contented with simply correcting the apparent deformity or malposition of the punctum in a case of stillicidium, but carefully explore the entire length of the canaliculus and nasal duct, to ascertain whether there is any deeper disease or coëxisting stricture. For a weeping eye may be due to a stricture deep in the nasal duct. This exploration should not be done, when it can be avoided, until the wound made in slitting the canaliculus has partly healed and become less tender.

I sometimes defer the deep exploration for a week or ten days, in the hope that Bowman's operation may suffice for a cure. To make this exploration, you need one of a set of Bowman's probes, or the probe known as Weber's, slightly bent, to pass readily beneath the overhanging brow, choosing in the case of the latter the smooth and not the notched one. Here, as in supposed stricture of the male urethra, make your first exploration with a full-sized probe or sound. By so doing, you ascertain at once the seat of stricture, and lessen the danger of producing a false passage.

A common seat of stricture is at the turn where the inferior canal empties into the lachrymal sac, and here, as in the strictures of the urethra, you may often overcome the obstacle by a delicate manipulation of your probe. As the thickening is almost invariably in the floor of the canal and of a nodular shape, you will usually pass it by: keeping the lid on the stretch, and depressing the handle of the instrument so as to press gently upwards towards the dome of the sac. If your probe does not readily enter, the ordinary strabismus hook will be found a useful explorer, and likely to pass where the former does not, and thus stretch the opening. After entering the sac and impinging against the opposite wall, you should carry the probe into a vertical position and gently pass onwards towards the nasal duct. As the extremity of your probe passes behind the edge of the maxillary bone, it approaches another common seat of stricture, and care is needed to prevent a false passage. Nothing is gained by violent pushing; a false passage may block the way to a cure.

From this point, and for somewhat more than half an inch, is the region of the most obstinate strictures that we encounter. In this region, known as the maxillary portion of the nasal duct, the mucous membrane is closely identified with the periosteum. Inflammatory processes agglutinate the two membranes, and not unfrequently lead to hyperplasia not only of the mucous membrane but of the periosteum of the bone.

If the stricture be permeable, I commonly pass a cylindrical laminaria probe, choosing a size that passes easily and yet fills the passage, and allow it to remain in until by swelling it has received an impress of the stricture. If, for instance, there is a single dense stricture, it will make a marked impression upon the probe, preventing it from swelling at a corresponding point, and thus furnishing not only a measure of the depth of the stricture in the nasal duct, but an indication of its firmness. If you propose to incise the stricture, you are thus enabled to pass your knife on without hesitation or uncertainty to its seat. Care should be taken in withdrawing the laminaria probe not to twist or bend it so as to break it off in the duct. Should such an accident occur, I would push the broken fragment onward into the nostril, or withdraw it upwards, by enlarging the Bowman's slit, so as to admit a pair of forceps into the tear sac. I have never had to resort to either expedient.

By the method indicated you have learned the seat and character of the stricture, and are now prepared to remove the real cause of the accumulation in the tear sac and backing up of secretion.

Some practitioners resort at once to a free incision of the stricture; others introduce a style made of leaden wire, fashioning its head so as to have it lie concealed in the open canaliculus, or bent over the edge of the lower lid, near the commissure, to be worn for weeks or months. Others again, by passing a full-sized probe every day or two, attempt to excite active congestion, and thus cause the thickened tissue to melt. I do not think that either of the three methods can be

so implicitly relied upon as to become exclusive. And here we must introduce another phase of disease of the sac and nasal duct before we can attempt to lay down rules for the treatment of stricture.

A neglected stillicidium and stricture leads sooner or later to progressive disease in the tear sac and nasal duct. A comparatively limited inflammation increases and spreads until the sac is stretched by accumulated fluid, its walls altered in shape and character, and a more or less acute dacryo-cystitis induced. Under these circumstances something more must be done than attempts to pass the stricture. Step by step, with efforts to dilate the stricture, must go measures to cure the catarrhal inflammation of the sac and duct.

Much harm has been unintentionally done by those who have advised persons affected with incipient tear-passage disease, not to have "the weeping eye meddled with." Such advice was not without justification in former days, when styles were in common use, but certainly very censurable in the present state of our knowledge.

Most of the uncurable cases now met with in practice are due to neglect, under the advice alluded to. Many a patient has gone for years, experiencing all the inconveniences and dangers of stillicidium, who might have been cured in three or four days, and with very little suffering. Many a patient, from the same cause, reaches a condition in which nothing but obliteration of the sac by surgical interference remains to be done.

No possible harm can result from the Bowman procedure when it is performed with becoming skill.

After noting the presence or absence of catarrhal inflammation of the sac and nasal duct, we should carefully explore the nares, and ascertain from the history whether there is naso-pharyngeal disease. Having ascertained these facts, we are then prepared to treat the case. I commonly begin by passing a full-sized probe, and washing out the sac and nasal duct afterwards with a solution of common salt, by means of a syringe, having a nozzle so small as to pass into or beyond the sac. In two or three days I repeat the procedure. If there is much muco-purulent discharge from the sac, I commonly wash out the sac with warm water, and then inject a solution of nitrate of silver, one or two grains to the ounce, every day or every other day, until the discharge loses its purulent character, when I repeat the probing. The moment I seem to gain anything by probing, I commonly intermit treatment to see if the new action induced will go on to a cure. I am convinced, from most careful observation, that in many cases the practitioner protracts his instrumental work in such a manner as to prevent a cure. A very few probings will tell us whether the case is one most likely to be cured by this method or the use of the knife.

Convinced of the propriety of the knife, I commonly employ for incising the stricture one resembling Weber's straight knife. To facilitate the procedure, I have had one made by Otto & Reynders somewhat longer in the shank than Weber's, and with about three-quarters of an inch of the shank untempered, so as to allow bending, to adapt the shape to a projecting brow. I like this knife better than Stilling's. It is smaller, and may be passed into a sac, and applied directly to a stricture without wounding other parts. (This and other instruments were exhibited to the members of the Academy.)

Stilling's knife, and all its modifications, cut not only where the stricture is, but where it is not, and I have after trial rejected them.

One free incision into a stricture is better than several, and I commonly cut into the projection, which causes me in passing the knife to deviate from the known course of the duct. This will be found sometimes on one wall and sometimes on another. I have said we must also examine the state of the nostrils. When there is any sign of naso-pharyngeal catarrh, I subject it to treatment by teaching the patient to wash out his nostrils daily with salt and water, and by doing it myself at my visits. I find it also beneficial to apply to the region of the nasal ducts in the nares an occasional application of sol. of nitrate of silver, thirty grains to the ounce—especially when the Schneiderian membrane is known to be thickened, as in catarrhal inflammation. In this matter, as in many emergencies of practice, I have been aided by the experience of my friend Dr. O. D. Pomeroy. As the object is to limit the application of the nitrate of silver solution to the needy part, a simple instrument recommended and used by the Doctor is of value. It consists of an ordinary Eustachian catheter, so bent at its objective end as to throw the contents where needed. By placing upon the manual end a soft rubber capsule, the Doctor has made a syringe which carries any desired quantity, from two or three minims of solution to ten or fifteen.

For free washing of the nares, I commonly employ the black rubber syringe, the bent nozzle of which is terminated by a flattened and perforated bulb, introducing the instrument behind the soft palate, and pressing the head of the patient forward at the moment of injecting, so as to insure a thorough irrigation of the nares. I prefer this syringe to any of the spray producers.

I have tried the method of treating nasal-duct stricture by lead styles, and cannot recommend it, except under the following conditions:—1st. When you have incised a stricture, a leaden style may be introduced and kept in place for a single day. 2d. In cases of diffuse inflammation of the nasal duct of a passive character, where the mucous membrane lining the duct is boggy, it may with advantage be left in for two or three days.

If allowed to remain in longer than this, it may induce or aggravate inflammatory changes in the mucous membrane, and produce new strictures or chronic ulcers.

I have had occasion to remove styles when others had introduced them, and found that they had by pressure and their irritating presence produced ulceration, thus seriously complicating the case. Moreover, they are not justified by the experience of those who in former times treated stricture of the male urethra by prolonged use of metallic catheters. Modern experience is conspicuously in favor of rapid treatment of strictures of mucous tubes by incision, rather than by slow dilatation. I would remark here, that the common practice of giving astringent slops to be applied externally as eye-washes, in cases of lachrymal disease, is not to be imitated.

Medicated collyria may do good in epiphora, where conjunctival irritation induces more lachrymation than can be disposed of, but not in the cases alluded to above.

It now remains to make a few practical suggestions in regard to acute inflammation and abscess of the lachrymal sac, and for the treatment of lachrymal fistula, and the operation for obliterating the lachrymal sac in incurable cases.

Our first view of a case may be when the tear sac is filled by accumulated inflammatory products, the superimposed connective tissue and skin widely inflamed, and all the symptoms of acute dacryo-cystitis present, complicated by an obstructive stricture, a

slight catarrhal inflammation having, by neglect, thus eventuated.

The common practice in such cases is either to make an error of diagnosis, and treat the case as incipient facial erysipelas, or, making a diagnosis, to order leeches over the sac and hot poultices. It is difficult to say which is the worse mistake. Either rests upon that sad tendency amongst us to generalize too hastily, not observing what we see, and the failure to analyse the objective and subjective symptoms in a given case. It being decided that the case is one of threatened or existing abscess of the sac, waste no time on leeches or poultices, they are both very bad; the first, and imperative indication, is to make an opening and let out the fluid. If this is not done, ulcerative perforation is almost sure to ensue, and with it such changes in the sac wall as to render the restoration of the integrity of the lachrymal passage almost impossible. If the matter is already showing itself as a yellow or bloody mark beneath the cuticle, your course is simple—cut through the skin at the most depending part of the fluctuating tumor. If you cannot see the matter through the skin, do not make this external opening—it is unnecessary, inelegant, and may lead to fistula, and should never be made if it can be avoided.

You have the choice of two other methods: either to slit up the lower canaliculus from punctum to sac, and thus evacuate the matter; or, if that be prevented by excessive swelling, to make an incision behind the commissure of the eyelids, between it and the caruncle, where you can reach the cavity of the sac with great ease, and still do nothing to embarrass you in the after-treatment of the case.

For this purpose I commonly take a small straight bistoury, or Beer's cataract knife, and stand behind the patient, so as to control his head. I open the lids as much as their swollen condition will allow, and then passing my knife so that its flat side grazes the eyeball, I pass it into the cavity of the tear sac, in the depression existing between the commissure of the lids and the caruncle. This point is rendered easier of access by the swelling of the surcharged sac, which causes the anterior wall of the same to bulge much in advance of its normal plane. You then may empty the sac without difficulty and avoid an external wound; nor does your procedure injure the canaliculi, or damage any appendage of the eye, or interfere with the after-treatment. Following the evacuation of matter, you recommend hot fomentations for an hour or so, and cool or cold water dressings, depending upon the grade of inflammation and the sensibilities of your patient. In old subjects the subsidence of the swelling of the connective tissue may be hastened by gentle pressure with dry lint and a single turn of flannel bandage.

In cases of lachrymal disease in young subjects, I would especially urge a very early slitting of the inferior canaliculus, as it will permit a free outflow of secretion from the sac towards the eye, diminishing the danger of ulcerative disease of the sac lining, and caries of bone. I always make this opening, even though I may not proceed farther with the treatment, considering it the best guarantee against abscess.

It will be necessary to give the young subject an anæsthetic for the operation, although commonly in the case of adults an anæsthetic is not needed in operations upon lachrymal diseases, except in the case of obliteration of sac.

The treatment of fistula-lachrymalis depends upon the state of the sac and nasal duct. If the fistula is due to a neglected but permeable stricture, you treat the stricture *secundum artem*, expecting when it is cured to see the fistula heal. If due to impassable, and therefore incurable strictures, or complicated by chronic suppurative inflammation and extensive ulceration of the sac, you must resort to the procedure remaining for the close of our remarks, viz., destruction of the lachrymal sac.

To destroy the sac, you must gain access to its cavity, and apply either the actual or potential cautery throughout its extent, and as far down the nasal duct as *possible*. Commonly, for this purpose, a free incision is made externally, extending from beneath the brow downward into the lachrymal sac, cutting the tendon of the tensor tarsi muscle, on over the maxillary edge of the orbit—a cut about an inch in length, attended by a good deal of bleeding, and usually leaving a more or less ugly scar—a scar always greater when the destruction of the sac is most complete.

I prefer, and have for years employed, the following procedure: With a Weber's knife I slit up both canaliculi from the puncta to the lachrymal sac. I then cut any sac wall that may intervene between the two canals. This carries me behind the tendon of the tensor tarsi; leaving it intact, I, with a strong small scalpel, make a sweeping cut upwards and downwards, so as to split the wall of the sac that looks towards the eye, until I can introduce a retractor into the cavity of the sac. When I can do so, I draw the anterior wall of the sac with the overlying palpebral commissure towards the side of the nose, and thus reveal the sac cavity. I then apply either nitric acid or potassa fusa to the sac lining and the canaliculi, until I feel sure that no living mucous lining is left. I then wash out carefully, allow the anterior sac wall and palpebral commissure to fall back into place, and the sloughing and inflammatory processes destroy both sac and canaliculi; nobody could tell from any external or conspicuous signs that an operation for the destruction of the sac had been done.

I think this method might be rendered still more acceptable by the use of some one of the elegant galvano-cauteries. I have frequently done this operation and never had any ugly inflammation or unpleasant result. It is a much more simple procedure than it may seem to be. When, therefore, we have a case of impermeable stricture or incurable inflammation of the lachrymal sac or nasal duct, especially when there is ulceration or extensive disorganization of the parts forming the passage, the sooner the sac is destroyed the better.

The presence of caries of the bone does not preclude the operation, but only retards the recovery.

In some instances of chronic lachrymal disease, we may have to resort to general medication suited to the diathesis; but, as a rule, the treatment is mostly local, with such attention to hygienic measures as will diminish the chances of annoying catarrhal complication.

I would, in closing, make the remark that some fail to have satisfactory results in the treatment of lachrymal diseases because they are too impatient. They are unwilling apparently to spend the time necessary to acquire dexterity in the use of instruments. They fall into the habit of rigidly following a favorite method, instead of studying the delicate shades of difference in cases, so as to adapt suitable modifications of treatment. They encounter obstinate cases, incurable cases, obstructive patients with impermeable mental or moral strictures, and are too ready to reject well-tried plans of treatment for deceptive novelties, or to adhere to useless and exploded practices.

Some among us cling like ivy to old ruins, and never rise above the level of antiquated notions. They go on the same old paths and congratulate themselves that their conservatism is the better wisdom, because,

forsooth, they now and then find progressive men looming up upon the horizon, as though they were laying a course to return to their standpoint.

ANTERO-POSTERIOR SYMMETRY, WITH SPECIAL REFERENCE TO THE MUSCLES OF THE LIMBS.

By ELLIOTT COUES, A.M., M.D., Ph.D.,.

ASSISTANT SURGEON, UNITED STATES' ARMY.

Article VI.

ANTIBRACHIAL MUSCLES PROPER—MUSCLES OF FOREARM AND LEG, ACTING UPON CARPO-METACARPUS AND TARSO-METATARSUS.

At the shoulder we saw muscles multiplied and diversified in relation to the perfect mobility of that joint, as compared with those conferring the greater stability at the hip. On the arm, we found fewer muscles, for simple flexion and extension at the elbow, while on the thigh more were required for the great strength exerted upon the knee-joint. At the distal extremity of either limb, where motion must be free and varied, muscles again increase in number and complexity. In the fore, the added power of motion is more diffuse; in the hind, it is more concentrated. Various and delicate muscular functions render the hand "fit instrument of the soul" of the animal

"—— quod dominari in cætera posset;"

singular disposition and action of the muscles of the foot only further obey the creative mandate that the same poet has signalized—

"Os hominl sublime dedit, cœlumque tueri
Jussit" . . . . OVID.

Man is the only truly bimanous and biped mammal; all others are pedimanous—quadrumanous—or quadrupedal—and the four extremities are used in progression.* We should infer, therefore, special modifications in either extremity, tending to obscure morphology; as is found to be the case. In the forearm and hand, there are more muscles than in the other limb, providing, first, for pronation and supination, second, for free and diverse movements of the digits. In the leg and foot, muscles are condensed, and have special lines of traction for better support of the body upright upon its narrow pedestals. But even in the obscurity that this embarrassment of riches brings, we may be able to point out more, and more striking, correspondences than would at first be supposed to exist.

As has been ably exposed,† the radio-ulnar articulation is a teleological interpolation, occurring in comparatively few animals; and all the pure accessories of the pronation and supination that this joint allows are to be looked upon in the same light. A singular corroboration of this view is also presented (*ibid.*, p. 301), taken from the disposition of the muscles themselves, as regards the sides of the limb they occupy; but this need not be given here. The *pronator radii teres* and the *supinator brevis* are the purest adaptive modifications among the muscles of the forearm. These have no posterior correlatives; at least, none have been discovered. The same may be said of the *pronator radii quadratus*, as far as the human subject is concerned.* The muscle called "*supinator longus*" is usually held to belong to the same group, from its function, and especially from its insertion into the styloid process of the radius. But this office is not well marked; and, for the matter of that, the biceps brachialis is a more powerful "supinator" than both of the muscles so-named together. The *s. longus* is really a muscle of the carpus, not of the forearm alone; in man, and in the animals nearest to him, its tendon is arrested on its way to the wrist, to which it normally goes, to be inserted into a carpal bone, or the base of a metacarpal, on the radial side. I therefore conceive it to be really a radial wrist-"flexor" (*i.e.*, *extensor* †) belonging to the superficial set of the *anterior* ‡ brachial region; regarded in this light, its posterior correlative is found. This point will be taken up again.

Before taking up the special flexors and extensors of the wrist and ankle, we may dispose of one obvious homotypy; I refer to that between the *palmaris longus* and the *plantaris*. These two muscles seem to vary inversely in point of size, &c., throughout the mammalian scale. In some pedimanous animals, they exhibit similar proportions in both limbs; then they lie on corresponding sides of the limbs (front of supine forearm and back of leg), in nearly the same relative position, and pass over front of wrist, and heel, respectively, to expand into, respectively, palmar and plantar fascia, of which they are tensors, besides being "flexors" (*extensors*) of the segments they reach. But in the horse, *e.g.*, where there is no palmaris, the plantaris is singularly developed, and simulates a flexor perforatus of the single functional digit.§ In man, again, where the palmaris is highly developed, the plantaris dwindles to an insignificant muscle, with a long delicate tendon, which, when it does not abort, goes to the calcaneal tuberosity, as a sort of accessory *tendo Achillis*.

Remembering how highly specialized man's hand and foot are; and that any multidigitate animal must have muscles, or at least tendons, superadded to those of beasts with only one functional digit, we may confidently look among the latter to find the simplest conditions of the problem, and learn by comparison what are the essential, and what the incidental, muscles. In the fore limb of a solidungulate, as the horse, four carpo-metacarpal muscles lie upon the forearm; these represent essential muscles, preserved with great constancy both in higher and lower animals. One at least of these four seems to include in itself certain muscles that in other animals are differentiated into distinct ones, and variously modified. These four exist in man; where they are known as the two (ulnar and radial) wrist-"flexors" (*extensors*), and the three (one

* With the apparent exception of certain saltatorial marsupials; but even the kangaroo is not strictly "biped," for the great tail gives tripodal support and locomotion.

† WILDER, op. cit., p. 28.

* But this muscle occurs in man in rather exceptional condition. In some other animals, it is a true interosseous muscle, extending between the radius and ulna nearly all or the whole way from wrist to elbow. In certain pedimanous beasts, especially those with movements at the ankle analogous to if not identical with pronation and supination, as, *e.g.*, the opossum, there is a large "interrosseus cruris" running obliquely between the tibia and fibula from ankle to knee; fulfilling in a measure the office of, and being homotypical with, the pronator radii quadratus.

† For convenience, and to lessen chances of perplexity, I shall give both names of the wrist muscles; the old recognized names in roman between quotation marks; the new proper names italicized in parentheses; thus—"extensor" (*flexor*) *carpi radialis longior*, &c.

‡ Although it is variously described as belonging to the "superficial posterior group" (Wilson), and the "radial group" (Gray). The latter is more nearly correct; but most of the "groups" and "regions" of the descriptive anthropotomist are irrational.

§ In this animal the plantaris "runs over the extremity of the os calcis, where it is enclosed in a sheath; passing on from this point, it divides, to be inserted upon each side of the posterior surface of the proximal phalanx towards its inferior extremity, here giving passage between its two insertions to the tendon of the long flexor of the toe; . . thus seeming to perform the functions both of the 'plantaris' and of the short flexor of the toes."—OWEN, *C. A. and P. Vert.*, iii, p. 37.

ulnar, two radial) wrist-"extensors" (*flexors*). With the former I consider the supinator longus, making six in all, for the correlatives of which we are to search. It will be observed, that the ulnar flexor and extensor are both single, and the radial double; but that the essential idea is of a flexing and an extending system on both ulnar and radial sides of the limb. I commence with the ulnar.

The antitype of the "extensor" (*flexor*) *carpi ulnaris* is the *tibialis anticus*. This has been long recognized and admitted, as evidenced by a synonym of the latter—*flexor tarsi tibialis*. They have the same action—flexion of their respective segments; they occupy the same relative position, arising from outer condyles, lying along homologous bones (ulna and tibia) and proceeding to the corresponding (inner) sides of hand and foot, respectively, to be inserted into bases of corresponding bones—fifth metacarpal and first metatarsal.

The antitypy between the "flexor" (*extensor*) *carpi ulnaris* and the *tibialis posticus* is almost as plain. The latter, indeed, used to be called "extensor tarsi tibialis." The objections, of the difference in the special origins of the two, and more particularly, of the fact that one is superficial and the other deep-seated, have less weight than the arguments in favor of the view here taken. In spite of the fibular origin of part of the tibialis posticus, it is essentially a tibial muscle, as the other is an ulnar one. Below, it gains the same relative position on the inner aspect of the ankle, that the other occupies on the wrist; passes behind the inner malleolus in front of other tendons, and lies along the inner margin of the metatarse. The tendons of the two are inserted in strictly homotypic positions upon the carpus and tarsus; and may be prolonged, in either case, to the corresponding meta-carpals and -tarsals. Finally, this identification seems required upon the principle of exclusion: no other muscle being found to correspond to anything like the same degree.*

Turning now to the radial side of the front of the wrist, we find the tendons of two muscles. One of these crosses the wrist to be inserted into the palmar aspect of the base of the index metacarpal; it is that of the "flexor" (*extensor*) *carpi radialis*. The other, in man, is arrested at the end of the radius; but under other circumstances acts upon the wrist. We have only to conceive the tendon of the supinator longus prolonged, as it really is in other animals, in front of the styloid process, to have another perfect radial "flexor" (*extensor*) *carpi*. Both these muscles, it will be observed, belong to the superficial group of the anterior brachial region; both proceed to the radial side of the front of the wrist; one arises from the internal condyle of the humerus, and the other from the external. Keeping these essential conditions in view, we look for the correlatives of these muscles in the components of the similarly disposed muscle of the calf that forms the tendo Achillis.

That this is a compound muscle, no one will question. The *soleus* and *gastrocnemii* were evidently morphological strangers, until brought together and fused in a common tendon. A further dissection of this composite muscle seems required; for in all probability the two gastrocnemii are morphological integers. It is to be remembered, that the consolidated calf-muscle of man is found in its most highly specialized phase; for here the two extremities are most widely differentiated. To see it in its typical condition, we naturally turn to some animal whose foot is most like its hand. A strictly pedimanous one furnishes the desired subject. In the opossum, I found the following condition: The soleus is absent; or at least so obscure that I did not recognize it. The two gastrocnemii are entirely distinct from origin to insertion. The *gast. externus* arises from the outer condyle of the femur and head of the fibula, and passes to be inserted by a long tendon into the *inner* side of the calcaneal tuberosity. The *gast, internus* arises from the inner condyle; its tendon passes down and crosses the other to be inserted into the *outer* side of the calcaneal tuberosity. Thus, including the tendon of the highly developed plantaris, there are *three* separate and distinct "Achillean" tendons, no one of which comes from a soleus. If this be the morphological condition of the calf-muscles, we are justified in concluding,—that the soleus is a teleological interpolation, having no correlative in the fore-limb; that the gastrocnemius internus is the correlative of the "flexor" (*extensor*) carpi radialis; and that the gastrocnemius externus is the correlative of the supinator longus.

These identifications may appear less forced the more closely they are scrutinized. The muscles in question of the forearm are strong "flexors" (*extensors*) of the wrist: those of the calf are powerful extensors of the ankle. The former both go to the outer (radial) side of the wrist; the latter to the os calcis, which is one of the outer (fibular) tarsal bones. Moreover, upon this hypothesis is explained the seeming anomaly, that there should be upon the forearm two radial wrist-"flexors" (*extensors*) arising from opposite humeral condyles; all others, whether flexors or extensors, arising together from the corresponding condyle.* If this determination be held inadmissible, it is difficult to see how the several muscles in question can be disposed of. There is nothing (outside the calf-muscle) to represent the "flexor" (*extensor*) carpi radialis. Wilder's reference to it of the *peroneus longus* is probably not to be admitted; since the latter is wholly external—condylar and fibular, and there is no evidence that such transfer sideways of the origin and position of homotypic muscles as this identification implies has taken place. The supinator longus would have either to be restricted to the forearm alone, where morphologically it does not appear to belong, and where it does not remain in many animals, or else be accepted as a dismemberment from the radial wrist-"extensor" (*flexor*) set, and so referable to one of the two longer peronei. Moreover, upon such disposition of these forearm muscles as this, the great muscles of the calf composing the tendo Achillis would be denied anterior correlatives; for reference of

* Owen holds the *gastrocnemius* to be the homotype of the "fl." c. uln., but apparently largely upon the unproven assumption that the calcaneal tuberosity represents the os pisiforme; that both these bones form powerful levers for the action of the two muscles, from both of which arise bicipital, &c. But the os pisiforme is the inner bone of the wrist, the os calcis one of the outer bones of the tarsus; and the gastrocnemius may be, as I hold below, better accounted for in another way.

The seeker after polar antitypies can do nothing with Owen's "serial homologies" of the muscles of the limbs. Thus he says (op. cit. i., p. 221), "when the leg is brought forward, widening the angle between it and the thigh, and when the fore-arm is brought forward, contracting the angle between it and the arm, the motions are the same, or homologous in both limbs;" but I hold, that they are not the same. This view obliges him to see correspondent muscles upon the *same* instead of opposite sides of the limbs: thus (l. c.) he says, "the biceps flexor cubiti, with the brachialis anticus, is the homotype of the triceps extensor cruris," &c.; which assuredly it is not, in any other than the serial mode of viewing the limbs. I should add, that, in taking, as he does, the fore-arm *prone*, and so in a morphologically false position, his "back of the fore-arm" is turned to the front of the animal; and in consequence, his "serial" homologies of forearm muscles, collectively considered, correspond to my antitypies; though, in homologizing individual muscles, he reaches conclusions different from most of those to which I have been brought.

* Referring to Wilson, p. 249, fig. 118; or to Gray, p. 306, fig. 172, one cannot fail to be struck by the resemblance of the fleshy parts of these two muscles to the heads of the gastrocnemii, or to note how the tendons converge to the radial side of the wrist, just as the gastrocnemii are blended in a tendon that passes to a fibular bone of the tarsus.

the compound gastrocnemius to the "flexor" (*extensor*) carpi ulnaris is impossible upon the hypothesis that forms the basis of reasoning on polar antitypy.

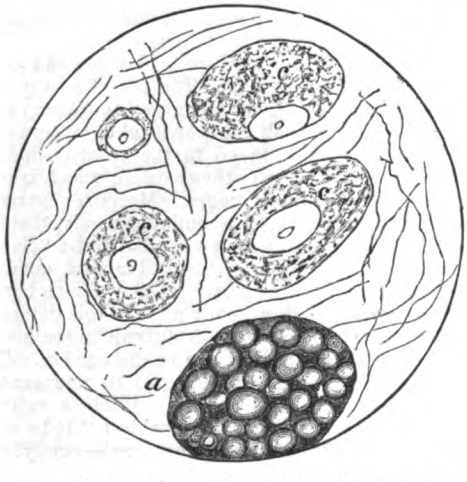
Examination of the remaining muscles of this group (rad. longior et brevior and the two peronei) is unavoidably deferred.

Reports of Hospitals.

KINGS COUNTY HOSPITAL.

MYXOMA OF THE PAROTID.

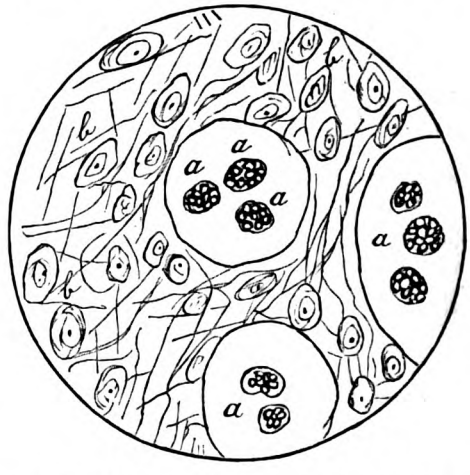
CATH. ———, aged about fifty-five years, has been afflicted for fourteen years with a morbid growth arising from the space between the ramus of the right lower jaw and the mastoid process. Eleven years ago a tumor was removed from the same locality, after three years' growth, by Dr. Turner, then resident physician of the hospital. Its nature was not determined, but its source was pronounced to be the parotid gland. Another tumor soon appeared in the same locality, and as a circumscribed induration was also noticed in one of the mammary glands, Dr. Turner pronounced the growth malignant, and advised that it should not be tampered with. It steadily but slowly increased in size until it reached five inches in diameter, encroaching on the cheek, lifting the ear on its surface, the skin covering it being full of plainly visible blood-vessels, and of a diffused red color, from more minute injection. Its size and painfulness became at last so aggravating that the patient clamored for its removal. Dr. Hutchison's advice was sought in order to settle conflicting opinions



respecting the propriety of its extirpation, and from the mobility and apparent independence of the morbid mass, he pronounced decidedly for an operation.

The patient having been etherized, Dr. Stiles dissected up a semicircular flap of integument, and removed a semilunar portion, so as to bring the cicatrix behind the jaw instead of on the cheek. Efforts to isolate the growth with the fingers and handle of the scalpel tore open a capsule which enclosed a cystic tumor of five inches in diameter, from which the latter was removed without difficulty. Several blood-vessels were twisted to arrest hemorrhage, and but one was tied. The wound soon healed, and the patient is rapidly regaining her strength.

On cutting open the mass it was found to be a cystic sarcoma or myxoma of Virchow. (See Morbid Growths, Art. I.) The mass, of the consistence of boiled white of egg, was filled with cysts of the size of a millet-seed, one only being of the capacity of two fluid drachms. The cysts were filled with an albuminous or mucous



liquid, transparent, of a straw color, which under the microscope was seen to contain a few compound granular bodies, (a) like those of inflammatory softening of the brain. It coagulated in alcohol in delicate membranous flakes as it exuded from the contracting mass. The stroma was of the kind of white fibrous tissue found in the umbilical cord and the vitreous humor of the eye, but here intermingled with oval, nucleated, and nucleolated cells. The cells were of very various size, few larger, however, than the one-thousandth of an inch, the nucleus being of the uniform size of the one-three-thousandth of an inch; the material of the cells was finely granular, delicate, and translucent; that of the nuclei, free from granulations and transparent. The nucleoli were not bright and variable like fatty granulations, but constant, uniform, and like those said to be distinctive of cancer.

As there are malignant as well as innocent myxomas, the prognosis in the present instance must be guarded, although the long duration of the growth, with absence of constitutional infection, is in the patient's favor.

As an indication of the source of the tumor, it is proper to note that large branches of the seventh pair of nerves, pes anserina, lay on the floor of the cavity from which the tumor was removed.

A REMEDY FOR UTERINE FIBROID TUMORS.—A favorite remedy with Dr. Atlee in these cases is the muriate of ammonia in doses of 10 grs., three times daily. Dr. A. R. Jackson can bear testimony to its apparent efficacy in one case, in which he used it in conjunction with the external use of the ungt. iodini comp. This treatment was persevered in for more than a year.—*Chicago Med. Journal.*

CANCER OF UTERUS.—Professor Fordyce Barker, of New York, advocates in those cases where there is extreme sensitiveness of the ulcerated surface, pessaries of iodoform.

℞. Iodoform.....gr. x.
Butyri cacao.....3 j.
Glycerine.....gtt. v. M.

One pessary. This also serves to correct fetor. A drachm of iodoform to the ounce of lard is also a beneficial ointment.

PRISONS AS REFORMATORY SCHOOLS.

THE report of the Inspectors of our State Prisons for 1870 shows these institutions to be in a reasonably flourishing condition. A great deal of necessary space is given to the financial exhibit of the managers, with the usual array of carefully-prepared statistics, which, in themselves of much importance, are nevertheless very dry reading. The physician and philanthropist, however, can gather from the documents in question much that is suggestive in reference to necessary reformatory measures. These latter are after all the main objects for which our prisons are instituted, and in proportion as they are attained by an intelligent and forbearing administration will the best good of society be subserved. The punishment of a State prison should consist more in the disgrace of being a convict, in the acknowledged necessity under which society has been placed towards the criminal to confine him, than for the performance of any special penalties afterwards. The latter are the proper preventives of crimes, and as such should be properly enforced by the strictest discipline; but beyond this every effort should be made to reform the criminal so that he may, on the completion of his sentence, be in a fair way to become a decent and law-abiding citizen. It is gratifying to note that both of the conditions are being met, and that experience has shown that the greatest good to the convict and to society is thus accomplished. Much harm has heretofore been done by a mistaken idea of what the discipline of a prison should be, and the tendency has always been to support it by punishments that have been unreasonably severe. The principle seems to have been more to avenge than to correct and reform, and the consequence has been to develop all the worst qualities of resistance in those upon whom such punishments have been inflicted. It has lately been shown that, with a few general exceptions, the best discipline is maintained by the fewest punishments, provided these latter are inflicted in absolute accordance with rules of the institution. Here is an explicit statement in support of the above from Dr. Arthur S. Wolff, the Physician in charge of the Clinton Prison:—

"Since the abolition of the shower bath by the legislative action of the last session, the punishments have been reduced at least sixty per cent. (!) Infractions of discipline are comparatively rare now. By order of the agent and wardens, a milder punishment has been introduced. Every act of disobedience or infraction of discipline is thoroughly investigated; the punishment is carefully considered and intelligently administered by the agent and principal keeper with a wise and honorable severity, but with swift and vigorous certainty. This generous sense of discipline, at once wise and humane, but firmly and impartially administered, never based upon meanness or fear, for the sole and determined purpose to curb the obstinate stubborn, and insubordinate, has had the most beneficial effect upon the convicts. They know what they have to expect if they commit a breach of the few and well-defined rules of the prison. He who knows anything of the peculiarities of the convict, is aware that it is not the remote chance of indiscriminate punishment that deters him from breaking or disobeying the prison discipline, but the more constant disagreement of vexatious and irritating rules. It is a matter of no small congratulation to the humanitarian and the philanthropist to know that for some time past I have observed the absence of that peculiar doggedness manifested in the convict, and which makes him so stubborn, and involves, always, more the spirit of resistance than the spirit of assault."

The experience of prison officials thoroughly accords with the above, and the question has been since the time of Howard, How much more can the severity of the usual punishments be curtailed consistent with the steadiness of a calm, rigorous, and resolute discipline? We have been answering this question in several practical ways during the past few years, but in none more directly and efficiently than by the abolition of the barbarous shower bath. While mental punishment is, theoretically speaking, to be considered the most salutary in its effects, we are nevertheless convinced that physical chastisement cannot be altogether dispensed with. There are certain natures and dispositions to which only physical suffering or discomfort can make any corrective appeal. To make these punishments effective the physician and humanitarian have as much and more to do than the prison keeper. The physical punishments, in order to subserve the proper purposes of discipline, must not, in the end, be detrimental to the health of the culprit. They should be severe enough to cause a dread of their infliction; at the same time their character should be such that in case of stubbornness they could be prolonged indefinitely. Nothing destroys discipline so much as being compelled, on account of an ill-advised method of punishment, to relax it in consequence of the physical intolerance of the subject without having attained its

primary object. It is, of course, exceedingly hard to inculcate the idea of dread for a punishment which in itself shall be mild; but the capability of its long continuance will in the end more than reconcile the two. Many of the mild chastisements employed in our prisons answer these requirements, while there are others which do not, and should be banished from the list. One of these latter is the dark cell in which incorrigible and refractory patients are usually confined. Although no corporeal punishment is inflicted, the patient is placed in a very dangerous situation in regard to sanitary requirements, and the longer he is kept there the worse are the conditions which surround him. The ventilation is next to nothing; and the air, aside from the ordinary contamination by breathing, is made almost poisonous by the admixture of the effluvia of the buckets into which the excrements are passed. In spite of the care that is exercised by the medical officers to have these apartments properly cleansed and policed, they are always unsafe in a sanitary point of view. The result is that almost always in cases where the executive officer deems it proper to confine a culprit for any considerable period, the physician has to release him to prevent disease and perhaps permanent ill-health. There are many other punishments which could take the place of this, and in being less dangerous to health, the better serve the purposes of firm and uncompromising discipline. The pernicious shower bath has been abolished—let the dark cell follow it into the past.

The crowded condition of our State institutions is another element which operates in a very unfavorable manner against reformatory measures, physical and moral. It not only helps to increase mortality and give a grave type to epidemics, but the compulsory association of criminals of different grades, which that want of room necessitates, is in the highest degree detrimental to the youthful portion of the population not yet hardened to vice. The proper separation of the different classes must, however, be a work of time; and if patience shall have done its perfect work and the end is accomplished, we shall take an immense stride towards reforming the criminal, in leading him by the shortest road to virtue.

Another evil in prison management, and which with a little care and forethought might be remedied, is the indiscriminate distribution of clothes. The changes, according to Dr. Wolff, are made:—"After being but imperfectly washed, because the officer having charge of that department cannot, with the best intention on his part, insure them from being saturated with foul and unwholesome emanations; in that state they are distributed without reference to the previous wearer. They may be clean as circumstances may admit, still they may have been worn by men who are afflicted with all kinds of transmittable skin diseases. They may still be impregnated with effete matter strikingly manifest to the senses." Bad as this is in a sanitary point of view, it is still worse in its moral aspect. On this point Dr. Wolff truthfully says: "Of all the paraphernalia of prison life, the striped apparel, the narrow cell, the labor, its crowded lock step, its stern discipline, the compulsion of wearing the shirt of another still reeking with the foul acid exhalations to the naked skin, *surpasses them all.*" We imagine nothing more calculated to prejudice the minds of the convicts against the good intentions of their keepers than this. There are many other points which might be discussed in a general way regarding prison reform, but as they hardly fall within the scope of sanitary reforms, we leave them for the moralist and political economist.

Reports of Societies.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

STATED MEETING, SEPTEMBER 5TH, 1870.

REPORT OF THE COMMITTEE ON INTELLIGENCE, BY BRADFORD S. THOMPSON, M.D., SEC'Y OF THE COMMITTEE.

MR. PRESIDENT—The following items are respectfully submitted:—

C. Handfield Jones, M.D., F.R.S., Physician to St. Mary's Hospital, London (*British Med. Journal*), reports an interesting case of "Influenza, with persistent headache and jarring sensation," relieved by the administration of bromide of potassium and a sternutatory. The patient, a male, æt. 29, millboard maker, had been ill between two and three months, and was treated by a medical man, who told him he had water-congestion on the brain, and blistered his neck and occiput. He was ordered to take two grains of quinine three times daily, and to use common snuff five times a day. The following day the subjoined *sternutatory*, recommended by Dr. Laycock, was substituted for the common stuff:—℞. Pulv. hellebori alb., gr. 40, pulv. cinchon. ʒ ss; and thirty grains of bromide of potassium and an ounce of camphor mixture were given every three hours. On the third day, his head was much relieved; the powder made him sneeze effectually, and some blood was expelled. On the seventh, ringing in the ear was gradually dying away. The headache was much less; what pain there was, was frontal. He was made an out-patient, and was last seen on the 15th, when he reported that he was almost free from headache. Much benefit was attributed to the hellebore snuff. The bromide had been continued in twenty-grain doses three times a day. Dr. Jones fancies that too many are inclined to look upon influenza as essentially a bronchial catarrh; but he agrees with Graves and Blakiston that its cause acts in a special manner on the nervous system, and that it is no mere inflammation. The peculiar prostration, the headache, and other nervous symptoms, which are not unfrequent, differentiate it markedly, besides the suddenness of invasion, which is often very remarkable.

As to the sternutatory, this must be regarded as a form of counter-irritation; having this advantage, however, that it is capable of repeated application within a short time, and that it provokes repeated diversions of blood, with mucous exudation. Its good effect in this patient depended, he thinks, on its producing reflex stimulation of the vaso-motor nerves of the cerebral arteries, and lessening the blood flow, which was probably excessive for the *weakened* tissue.

Syphilitic Disease Affecting the Nervous System.—The editor of the *Dublin Quarterly Journal of Medical Science* writes as follows in regard to Thomas Reade, M.B., who was the first to prove that epilepsy, mania, hemiplegia, paraplegia, amaurosis, hebetude of intellect, loss of memory, cranial neuralgia, suicidal propensity, paralysis of sphincters—all may be the offspring of the one disturbing cause—syphilis affecting the nervous centres:—It is very generally known that Dr. Thos. Reade, of Belfast, published his first paper on syphilitic diseases of the nervous system in the pages of this journal in the year 1852, Dr. Todd, of London, having drawn attention to the same subject in 1851. All, however, are not aware of the fact that Dr. Reade's paper was offered for publication in the year 1847. Thus Dr. Reade was really and literally the first who recognized the existence of syphilitic disease of the nervous system; and his labors since this time in further elucidation of the same are well known, and should be freely acknowledged.

Dr. Reade (*British Med. Journal*), in explanation, states that he offered his first series of cases in 1847 to the editor of the *Dublin Quarterly*. He, however, refused the paper, and it lay with him until accident introduced him to Dr. Neligan, the next editor of the same journal, who asked him if he could give any contribution. The rejected paper was named, which he gladly accepted, and published in February, 1852. By Dr. Neligan's desire, a second series of six additional cases was published in 1860.

The knowledge of the subject in 1867 had acquired such a full recognition in England and on the Continent that he collected his series of papers and additional cases—in all twelve—and published them in a volume.

In conclusion, the claim of priority or precedence bears no weight on his mind. The acceptance and reference, by *modern writers* on syphilis, of his cases, as faithful and instructive types of syphilitic disease dominating the nervous system, could alone be to him a justification for publishing a retrospect.

AN IRON COTTAGE HOSPITAL.

Dr. W. Jones, of Aspatria, England, at the late meeting of the British Medical Association, held at Newcastle-upon-Tyne, gave a description, and exhibited a model of a moveable metal cottage hospital, which he had designed. The building, as at present arranged, consists of a central square tower, the length of each of the sides being 16 feet. The tower is 33 feet in height (this being the thirty-third year of Her Majesty Queen Victoria's reign), including three stories with a spiral ascending staircase in the centre. Such a building is capable of being readily erected or removed at pleasure; and when any locality may be visited by an epidemic disease, so that it would be next to impossible to convey patients to a hospital at a distance, the operation may be reversed by conveying a hospital to the patients.

We would also remark, that on each of the three sides of the tower is a ward of the same dimensions as the base of the tower. Each ward is 12 feet in height from the ground floor to the eaves, and 24 feet to the roof-tree; and is calculated to contain three beds. The number of cubic feet of air allotted to each patient is 1536 feet. Attached to each of the wards on the outside is a corridor, entered from the end of the ward, for the use of patients during convalescence and during unfavorable weather; it may also be devoted to closet or bath arrangements. The use of the earth-closet has been suggested.

Form of Neuralgia of the Jaw Bones, Hitherto Undescribed.—Prof. S. D. Gross, M.D., Philadelphia (*Am. Jour. Med. Sciences*), describes a form of neuralgia of the jaw bones, which, so far as his information extends, has not hitherto been described. Its seat is in the remnants of the alveolar process of edentulous persons, or in the alveolar structure, and in the overlying gum, and is met with chiefly, if not exclusively, in elderly subjects. It is also more common in the upper than in the lower jaw. The part affected is usually very small, often not exceeding a few lines in extent. The soft tissues around do not seem to suffer, at least not in the same degree, as is so frequently the case in the more ordinary forms of neuralgia of the jaws and face. On the contrary, the morbid action is generally limited to the osseous structure. In rare instances there may possibly be some involvement of the gum, which is nearly always exceedingly hard and dense, grating more or less under the knife, and adhering with extraordinary firmness to the atrophied alveolar process beneath.

The pain is generally paroxysmal, coming on in fits and starts, very much as in ordinary neuralgia, the slightest causes being sufficient to provoke it. Pressure generally relieves rather than aggravates it.

The pathology of the affection seems to be compression of the minute nerves distributed through the wasted alveolar process, dependent upon the encroachment of osseous matter upon the walls of the canals in which they are naturally inclosed. In the natural state the nervous current passes along without any hindrance, but in this condition of the canals in question its transmission is interrupted, and more or less pain, known as neuralgic, is the consequence.

The disease usually comes on gradually, and proceeds from bad to worse, until, in many cases, the suffering is rendered nearly intolerable.

Prof. Gross adds five cases of this affection, with their treatment, and believes that the only effectual remedy is excision of the affected alveolar process. No particular attention need be bestowed upon the after-treatment. A mild course of chalybeate tonics may be required when the patient is anæmic, or affected with flatulence and indigestion. He also exhibits a pair of forceps made for the removal of the alveolar process.

Coincidence of Certain Nervous Symptoms with the Presence of an Excess of Urea in the Urine.—F. A. Burrall, M. D., New York City (*Am. Jour. Med. Sciences*), publishes an instructive essay on this subject, containing observations which have not been previously reported in America. In the three published cases of general malaise, vertigo, and acidity, complicated with a peculiar variety of nervous symptoms, the patients showed a marked *excess of nitrate of urea*.* The advantage of studies like that which compose this paper is, that they tend towards increased knowledge of the essential nature of disease, and remove our practice farther from empiricism. The necessity is often felt in treatment of keeping the diathesis of the patient in view without looking for a particular set of symptoms, which only appear when the diathesis is fully developed. The test for nitrate of urea is one which may be employed by any general practitioner, and is valuable in differential diagnosis as aiding us in distinguishing between nervous symptoms resulting from anæmia and those which accompany an excess of urea in the urine.

This study also suggests the necessity of examining the urine in cases of vertigo, to see if this symptom may not be one of the many in which uric acid or its congeners may manifest itself. It would also be well to

* While alluding to this class of cases in the presence of Dr. H. C. Farnham, of this city, this gentleman showed him a copious deposit of nitrate of urea from a patient laboring under intense nervous depression. Thus corroborating his experiments.

see how far sleeplessness may, in some cases, depend upon a similar cause. Dr. B. has found the spiculated crystals of urate of soda in the urine of puerperal mania.

We may, besides, be led to inquire as to how far those alkaline remedies, such as muriate of ammonia, valerianate of ammonia, and bromide of potassium, often so efficient in nervous disorders, owe their effects to the combination, with a nervine, of one of the alkalies which combine with or dissolve uric acid.

SPECIAL MEETING, SEPTEMBER 26TH, 1870.

DR. JOHN R. VAN KLEEK in the Chair.

INFLUENCE OF MUSCULAR EXERCISE ON THE URINE.

DR. AUSTIN FLINT, JR., read a paper entitled, *The Influence of Excessive and Prolonged Muscular Exercise upon the Elimination of Effete Matters by the Kidneys; based on an Analysis of the Urine passed by Mr. Weston while walking One Hundred Miles in Twenty-one Hours and Thirty-nine Minutes.*

When Mr. Edward P. Weston was performing his great pedestrian feat, at the Skating Rink in this city, last May, Dr. Flint visited the rink near the close of the hundred-mile walk. He learned that, by chance, all the urine passed during the walk had been collected in a single vessel. This was placed at his disposal and subjected to a careful quantitative analysis. The observation being entirely unpremeditated, certain elements of scientific completeness were lacking, such as the exact amount of food and drink consumed, etc.; and the specimen of normal urine for comparison was necessarily obtained, not before the walk, but some three months later, when the conditions seemed perfectly satisfactory.

It was evident that an accurate comparison of the urine passed during such an enormous strain upon the muscular and nervous systems, under known conditions of diet, etc., with the normal urine under known conditions, would be of great importance to science; especially since the observations of Fick and Wislicenus, Haughton, and others, had tended to throw doubt upon the commonly received view that exercise increases the elimination of urea.

Mr. Weston is 31 years old; of medium height, rather slight; ordinary weight, without clothing, about 122 pounds. From his professional occupation, his hours of sleep and eating are quite irregular. He has never taken a course of "training," preparatory to his feats of endurance. His general health is perfect. At the time of the walk he was in "fine" condition, and his weight was five pounds less than ordinary.

The conditions during the walk were, as nearly as could be ascertained, the following:

Weight of body, without clothing, 117 pounds.

Food and drink taken: Beef essence, between one and two bottles; oatmeal gruel, two bottles; sixteen to eighteen eggs, raw, in water; lemonade, about half-a pint; champagne, about three fluidounces; brandy, two and one-half fluidounces; water to rinse mouth every few minutes, but little swallowed.

No sleep; no alvine evacuation; perspiration slight.

The urine passed during this time (counted as twenty-two hours) measured 73½ fluidounces (estimated for twenty-four hours at 80 fluidounces); acidity normal; color light canary; odor strongly urinous, but normal; specific gravity, 1011.55; no abnormal matters; microscopical examination negative. Analyzed by the methods detailed in the speaker's manual of the "Chemical Examination of the Urine," its composition per fluidounce was found to be:

Urine of Exercise per Fluidounce.

Urea	5.779 grs.
Chlorine	1.120 "
Sulphuric acid	0.920 "
Phosphoric acid (total)	1.504 "
Phosphoric acid (with alkalies)	1.280 "
Phosphoric acid (with earths)	0.224 "
Uric acid	0.500 "

The conditions during the twenty-four hours, 6 P.M. to 6 P.M., selected for collecting the standard specimen of urine for comparison, were as follows:

Weight, naked, 122 pounds.

Food and drink: Supper—Pickled lambs' tongues, warm light biscuit, one cup tea. Dinner—Cold corned beef, hot bread-cakes, one slice bread, one cup coffee. One glass effervescing root beer, and two cigars during day. Had eaten salt ham three hours before the beginning of the selected twenty-four hours.

Sleep between eleven and twelve hours; one alvine discharge (no urine lost).

The urine passed in the twenty-four hours measured 33 fluidounces; acidity rather faint; color light canary, slightly turbid; odor strongly urinous, but normal; specific gravity 1025.43; no abnormal matters; decomposition rather rapid; microscopical examination showed slight excess of mucus, otherwise negative. Analyzed by methods identical with the last, the composition per fluidounce was found to be:

Urine of Rest per Fluidounce.

Urea	5.800 grs.
Chlorine	3.360 "
Sulphuric acid	1.440 "
Phosphoric acid (total)	0.960 "
Phosphoric acid (with alkalies)	0.640 "
Phosphoric acid (with earths)	0.320 "
Uric acid	0.680 "

The Urine of Exercise, calculated for twenty-four hours, is compared with the Urine of Rest for twenty-four hours in the following table:

Urine of Rest and of Exercise for Twenty-four Hours.

	Rest.	Exercise.
Total quantity	33.000 fl. oz.	80.000 fl. oz.
Urea	191.400 grs.	463.368 grs.
Chlorine	110.880 "	89.808 "
Sulphuric acid	47.520 "	73.776 "
Phosphoric acid (total)	31.680 "	120.600 "
Phosphoric acid (with alkalies)	21.120 "	102.600 "
Phosphoric acid (with earths)	10.560 "	18.000 "
Uric acid	22.440 "	40.080 "

After making all allowances for differences of diet and other conditions, the speaker concluded that the severe and prolonged muscular exertion must be credited with producing a decided increase in the amount of water eliminated by the kidneys; an increase of from seventy-five to one hundred per cent. in the amount of urea eliminated; a considerable part of the increase in the sulphates and phosphates; and an increase of about seventy-eight per cent. in the uric acid. The diminution of the chlorides seemed pretty well accounted for by the diet.

For further calculations from the above data, and a more detailed statement of the points involved, we refer the reader to Dr. Flint's paper, which is to be published.*

The Society adjourned.

---

* It appears in the *New York Medical Journal* for October.—ED.

SIXTY-FIFTH ANNIVERSARY MEETING, OCT. 3, 1870.

DR. JOHN R. VAN KLEEK in the Chair.

IN the absence of the President and Vice-President, Dr. Van Kleek was chosen President *pro tem.*

The minutes of the Comitia Minora for the year were read.

The Treasurer, Dr. BIBBINS, presented his report, showing a balance on hand of $434.06.

The following letter from the President, in response to the resolution passed at the meeting of 5th September, was read by the Recording Secretary:

GARRISON'S-ON-HUDSON, Sept. 16, 1870.

DR. PURDY, *Recording Sec. N. Y. County Med. Society:*

MY DEAR DOCTOR: I have the honor to acknowledge receipt of the resolution of the Society, conveying their sympathy with me in my recent illness, and their kind and friendly wishes. I am very grateful to the Society for their action in the matter, and am happy to assure them that my improvement justifies the greatest encouragement for the future, and the hope of speedy restoration to health. With the kindest regards for yourself, I am

Yours very truly,

GEORGE T. ELLIOT.

ELECTION OF OFFICERS.

The Society proceeded to ballot for officers, and the following were elected for the ensuing year:

President—Dr. Abram Jacobi.

Vice-President—Dr. Austin Flint, Sen.

Recording Secretary—Dr. Alfred E. M. Purdy.

Corresponding Secretary—Dr. Bradford S. Thompson.

Treasurer—Dr. Wm. B. Bibbins.

There being only a partial choice of Censors and Delegates to the State Society, further balloting for them was postponed to the next meeting.

NEW BY-LAW.

The following By-law, proposed at the last stated meeting, was adopted:

CHAP. I., ART. —.—Members whose dues are unpaid shall not be candidates for any official position in the Society, nor shall they be entitled to vote.

The Society adjourned.

ADJOURNED ANNIVERSARY MEETING, OCTOBER 10, 1870.

DR. T. GAILLARD THOMAS, Vice-President, in the Chair.

ELECTION OF OFFICERS CONCLUDED.

THE balloting for Censors for the year, and for Delegates to the State Society to serve for four years, was resumed and concluded. The following is the complete list of those elected:—

Censors.—Drs. Ellsworth Eliot, George T. Elliot, T. C. Finnell, J. C. Peters, Stephen Rogers.

Delegates.—Drs. Thomas S. Bahan, Nathan Bozeman, Salvatore Caro, William M. Chamberlain, Jean F. Chauveau, James J. Connolly, George T. Elliot, Thos. A. Emmet, Abram Jacobi, E. Lee Jones, Herman Knapp, Ernst Krackowizer, Robert Newman, Robert J. O'Sullivan, John C. Peters, Alfred E. M. Purdy, Stephen Rogers, James Ross, Andrew H. Smith, Bradford S. Thompson, William T. White.

The Society adjourned.

NEW YORK ACADEMY OF MEDICINE

STATED MEETING, SEPTEMBER 15, 1870.

DR. H. D. BULKLEY, PRESIDENT, in the Chair.

THE President announced the following names of deceased members of the Academy, who had died since the last Stated Meeting: Drs. James Warren, of Madison, N. J., æt. 76; John Shanks, N. Y., æt. 69; and Ex-Prof. Gunning S. Bedford—all old members.

DR. C. R. AGNEW then read an interesting paper on "*Practical Suggestions for the Treatment of Lachrymal Diseases.*" *Vide* page 366.

DR. D. B. ST. JOHN ROOSA remarked that he felt sure that he expressed the sentiments of the members present when he testified his appreciation of the résumé of Dr. Agnew's large experience in lachrymal disease which he has just given us.

There were one or two points in the paper to which he would like to add a word. He very well knew that, as Dr. Agnew had said, the surgical experience of to-day favored the rapid dilatation of stricture of mucous canals, and yet it was only lately so. The speaker well remembered, during his pupilage in the New York Hospital, where there were always a large number of cases of so-called impermeable stricture, the injunctions of Professor Van Buren to exhaust every effort by means of fine bougies and the well-known adjuvants to pass the stricture, before any resort to a cutting operation, and to continue the treatment thus begun, in the same way; and although surgeons with Dr. Van Buren have changed all that now, the good results he then saw and experienced had so impressed themselves upon him, that in the treatment of lachrymal stricture he had carried out these teachings.

Professor ARLT, of Vienna, in a monograph known to many of us, states that he is inclined to think that a lack of patience is the cause of many failures in the probe treatment, where excision of the lachrymal gland or lachrymal sac was resorted to for the cure of obstinate disease of this part.

His own experience, which had been, in common with all those who see much of eye disease, proportionally large in lachrymal affections, had been gratifying, even with full allowance for the favor with which one's own results are viewed.

Just one other point: While it must be admitted that in some cases naso-pharyngeal disease is coincidental with, and perhaps the cause of lachrymal affection, he thought it a fact going to show that it was not, perhaps, as common a cause as indicated or expressed in the paper, that in a large number of ear cases springing from catarrh, very few if any cases of lachrymal disease were found. As near as he could state without his notes, he did not remember one case in which catarrh of the middle ear was coincidental with lachrymal disease. The necessity of treating the naso-pharyngeal space was perhaps not always prominent. He would, however, re-echo what Dr. Agnew had said, in regard to the value of Dr. Pomeroy's instrument, which he considered the best for making applications to the mouth of the Eustachian tube that we have at hand.

DR. H. KNAPP.—Not having the honor of being a member of the Academy, allow me, Mr. President, to express my gratitude for the kind invitation to take part in the discussion on the important subject under consideration. I have attentively listened to, and am highly pleased with Dr. Agnew's paper. He entered thoroughly into the treatment of a group of diseases, which are exceedingly troublesome to the practitioner. Above all, I was delighted to see the doctor have due regard to the causes of lachrymal diseases. I cannot but agree with his views, and am sorry that I must differ from what Dr. Roosa said on this subject. If we do not admit that strictures of the nasal duct and their consequences are primary affections—and I think they are no more primary affections than strictures of the urethra—they must result from diseases either of the conjunctival or the Schneiderian mucous membranes. You may watch the multitude of conjunctival af-

fections that throng the New York Eye Dispensaries every day, and you will but very rarely see a case of blennorrhœa or trachoma complicated with a disease of the tear passages. Lachrymal affections must, therefore, start from the nose. I fully agree with Dr. Roosa's assertion that patients suffering from aural catarrhs, the origin of which, as is known, lies mostly in the region of the orifices of the Eustachian tubes, are not more the subjects of lachrymal difficulties than other people. But with regard to the extension of morbid conditions, the upper pharyngeal and posterior nasal region may be regarded as a space for itself, the diseases of which show a marked tendency to continue through the tube into the cavity of the tympanum, but have no great tendency to spread forward to the nasal passages or downward to the larynx. Physicians in general practice and specialists for throat diseases will testify, that patients suffering for years from laryngeal affections are not at all particularly liable to become hard of hearing, as would be the case if the diseases of the laryngeal mucosa had a tendency to extend upward. According to these views I consider it very rational to attack lachrymal troubles from the nasal mucous membrane. With Dr. Agnew, I am very much in favor of the posterior nares syringe, but employ it especially in ear diseases, while in those of the tear passages I should prefer the application of atomized astringents through the nostrils.

Another point in Dr. Agnew's paper with which I was particularly pleased, is his method of obliterating the lachrymal sac by slitting up the canaliculi and enlarging the wound through the membranous portion of the sac sufficiently to introduce the caustic. It closes the canaliculi with a certainty, avoids a scar in the skin, but may have the disadvantage that superfluous caustic may injure the eye-ball more easily than when the substance is put into the sac through an external wound, the eye-ball being protected by the closed lids.

I cannot lay so much stress as Dr. Agnew does on the advantages of opening abscesses of the lachrymal sac from the conjunctiva. By this method the canaliculi may be injured, and the fibres of the musculus compressor sacci lachrymalis severed, perhaps, to such an extent as to render the absorption of the tears incomplete. Besides that, I may say that an incision of the lachrymal sac through the skin heals very readily, leaves a scar only perceptible on close examination, and has the advantage to cut the cavity at its lowest portion, which renders the evacuation of the contents easiest.

I waited most anxiously to hear Dr. Agnew speak on one particular morbid condition of the tear passages, which covers the majority of the cases of lachrymal difficulty that come before the practitioner, and, by their obstinacy, are more troublesome than all the others—I mean the dilatation of the lachrymal sac in form of a diverticle. Even when by nature or medical treatment the nasal duct is rendered perfectly free, the tears will trickle down from the inner mouth of the canaliculi along the membranous wall of the sac, fill the diverticle and obstruct the upper end of the nasal duct. Thus epiphora is kept up, although the nasal duct be free, and, by stagnation of the muco-serous fluid, a predisposition is sustained for different kinds of inflammation in the sac and its surroundings. All attempts to obviate this annoying condition have hitherto failed. The most rational among them seems to me a proposal from Mr. Critchett of London, viz. to remove the diverticle by partial excision of the membranous wall of the sac. Although I do not recollect that the performance of this operation has been recorded, I have no doubts that in hands so skilled and experienced as those of Dr. Agnew, it must prove successful. And if it be successful, the cure of that most annoying difficulty will not merely be palliative, but a restitution of integrity.

Dr. O. D. Pomeroy stated, that the prominent indication, it seemed to him, in the treatment of the tear-duct, was to restore not only the natural calibre of the tube, but to induce a healthy condition of its mucous lining. To this end the probing should be performed with very great care, so as not to inflict undue violence on the part.

He well remembered treating a case of Dr. Roosa's, for him, in which an entire cure was effected by probes not exceeding the size of No. 3, when frequently Nos. 8 or 10 are introduced. When we reflect on the extreme minuteness of the lachrymal puncta, hardly large enough to introduce a pin's point, we readily see that size of canal is not as essential as the quality of the duct.

He had seen a No. 8 probe easily enter a tear-duct which would not admit a drop of tear, on account of the roughness of the canal walls, together with a boggy-like condition of things. A tube to convey a fluid must have smooth sides, its calibre must be at all times pervious, without the need to be stretched to induce a tubular form.

The knife with which the operation is done must fulfil several conditions. The one he has used latterly, and the best he has seen, is shaped like a grass sickle, although not as crooked. The point should be rather finely probed, so as to obviate the necessity of dilating the punctum by another instrument, as recommended by Soellberg Wells and others, the probed portion not extending back more than $\frac{1}{10}$th of an inch; the end of the cutting portion being very narrow—as narrow as well can be made—so that the instrument may be insinuated into the canaliculus almost as readily as a probe itself; otherwise there is danger of lacerating the mucous lining, or of making a false passage. The cutting edge extends as near the end of the instrument as possible, so that no portion of the duct may remain undivided, for it has been already shown that a favorite point of stricture is where the canaliculus joins the lachrymal sac.

With the method of treatment by injections from above, he certainly had not been very successful. It seemed as though the cases requiring special treatment of catarrhal conditions, contra-indicated much probing, and the nozzle of the most delicately-constructed syringe must irritate almost as much as the probe.

If there was any proposition which might carry with it a good degree of conviction, it was this: that naso-pharyngeal catarrh might, and very frequently did, travel up the Eustachian tube to the tympanic cavity, involving perhaps every part of the auditory apparatus, and in some instances extending to the brain itself.

In this condition of things it was a well-established fact that a strong solution (30 to 80 grains) of nitrate of silver, applied by the method suggested by Dr. Agnew, will not only *cure* the inflamed and occluded tube, rendering it pervious, but the inflammation of the tympanic cavity may succumb to this mode of treatment; but he is careful to avoid injecting the fluid up the tube to the cavity.

Applying this idea to the condition of the tear-duct, it would seem plausible that a similar course of treatment would be available here, provided the causation of the trouble lay in the throat and nostrils, which might be demonstrated in numbers of instances to be the case. The treatment of the general catarrhal condition would benefit the catarrh of the tear-duct, but if the application was made directly over the nasal extremity of the duct, much more benefit would result.

For this purpose the tube spoken of by Dr. Agnew was, so far, the best he knew of, although he felt a reluctance at its being so fully indorsed, as his studies in that direction had been insufficient for positive conclusions.

The tube should be passed along the floor of the nares with the outer extremity much elevated, so that the bent tube might hook beneath the overhanging inferior turbinated bone, and passed backwards about three-quarters of an inch. The difficulty was in the variable position of the canal. If, however, the injection was thrown near the mouth of the tube it would do very well.

In concluding, Dr. Pomeroy asserted that in old cases of catarrh a very strong solution of nitrate of silver was well borne—80 to 100 grains to the ounce. Weaker applications were often inefficient.

On motion of Dr. Post the Academy adjourned.

Correspondence.

THE THERAPEUTIC USES AND ABUSES OF QUININE.

To the Editor of the Medical Record.

Sir—Of course we read attentively the letter from Dr. Roberts Bartholow, which you published in your issue of the 15th Sept., 1870. We always read what he writes on the subject of quinine; and we generally read what comes in our way of his writings on any subject, even his letters at various times. This habit, perhaps, will account for the fact that we were not surprised by anything we read in this last letter. But for the apparent expectation on his part, that a certain query he propounds, be replied to, we find no reason to annoy you or the readers of the Record with a response to that letter. The query centres on the provocation we had for the preparation of our paper on the "Uses and Abuses of Quinia and its Salts," published in the 20th vol. of the Transactions of the American Medical Association. We hasten to gratify this laudable curiosity by stating that he is not entirely exempt from the responsibility of contributing to provoke it. But it is due to him to add, that such provocation was neither direct nor personal. His, and others' papers upon the subject of quinine and its relations to miasmatic poisoning and disease, containing statements discordant with our own belief as to the truth in important points of the subject, provoked us to record the results of our experience and study in highly miasmatic regions. We presumed that an aggregate large hospital and private practice of ten or twelve years, and much of the time in one of the most intensely miasmatic localities in the world, would be conceded as sufficient to give us a right to an opinion on this subject; and upon this presumption, we have ventured to record the truth as we comprehend it. If in so doing, we have referred, by way of illustration, to the statements of other authors, in such terms as to displease, the provocation has certainly never been of a personal nature. This we wish here to distinctly avow.

From the circumstances of our professional history above alluded to, we ventured to hope that the profession would regard us as excusable for entertaining some definite and systematic, and, perhaps, very positive ideas about the use of quinine in miasmatic exposure, and miasmatic infection, and miasmatic disease; and these anticipations had led us to hope that any warmth of expression we might be induced to employ in pointing out what we regard as important facts, or in calling attention to what we might regard as serious errors in the doctrines or in the writings of others, might not be attributed to other motive than the true one—viz., of stating the truth as we honestly understand, in the most forcible way. Those only who know, or think they know the truths, are annoyed at seeing statements which conflict with those real or supposed truths; and we apprehend that such may be pardonable if they occasionally exhibit a little vehemence. Of such a character the foot-notes to my paper on quinine—which appear to have been especially offensive to the author of this letter—sometimes perhaps are. But we now hope that he understands their provocation and motive. They are not personal. We do not believe in the doctrines he promulgates, and we say so distinctly. We seriously believe the practice he teaches to be dangerous, and we declare it. But now, in his letter, he no longer confronts us with his own experience and alleged research, but instead, shelters himself behind the "*ablest clinician in the United States*" (italics our own), and behind sundry other foreign ones, no doubt in their day equally able; all of whom do not agree with us as to the hour and the method of administering quinine in intermittents, but do agree with him. Upon this matter we would respectfully remark that, we went into practice well-nigh twenty years ago, fully convinced of the correctness of the teachings of these able "clinicians;" but time and an unusual field of observation, aided by the guidance of equally able practitioners with those named in said letter as his authority and shield, convinced us that those teachings are incorrect, those doctrines unfounded, and we have thought it our duty to communicate that conviction to the profession. We therefore stand upon our own platform; and while he is at perfect liberty to defend the eminence of his authority, we hold ourselves in readiness to demonstrate the truth of our declarations by the test of actual practice, willing to stand or fall with their success or failure.

We find that he has inexcusably, perhaps perversely, fallen into a somewhat serious error in assuming that our "knowledge of malarial disease is entirely clinical;" that we have not taken the trouble to inform ourselves "in the present state of scientific opinion in regard to the changes induced by malaria in the organism." Our connection for many years with hospitals devoted almost exclusively to the care of persons who had been for months or years infected with miasm, gave us ample and improved opportunity for microscopic investigation, of which he is at liberty to make a note, and to add that we made these investigations before he did science the service to compile material upon this subject. Our excuse for not treating the subject in the body of our paper on quinine is, that we deemed it improper to encumber a paper on materia medica and therapeutics with discourses upon morbid anatomy and pathology. We have not thus far found any reason, neither in anything contained in his contributions, nor in those of the very eminent authority he alludes to—and with whose views we beg to assure him we are acquainted—to change our original assertion, viz.: "It is quite gratuitous to suppose that because paroxysms recur from time to time, it is on account of structural changes in the organs of the body, especially of the liver and spleen." We have certainly found these organs free from any appreciable pathological condition, in many cadavers of persons who for years before death were the victims of frequently recurring paroxysms of ague. Neither on the subject of the pathology nor the treatment of miasmatic disease, therefore, do we yet find need for his, no doubt kindly meant, suggestion, that we re-

view our experience, which he pleases to characterize as "enormous." Again, it is true that in our paper on quinine we noted that Dr. Bartholow had not, in his paper on the same subject, alluded to its use in erysipelas—a fact which, in his letter, he does not dispute. As we regarded the use of the medicine in this disease as one of its most *important* uses, we thought it a proper means of fixing professional attention to it, by noting that a writer of his pretensions had not mentioned it. We still think it was a proper means, and it is certainly manifest that it has fixed the attention of at least one member of our profession to the fact. To this means the profession is most undoubtedly indebted for his effort to show that, though he did not allude to the use of quinine in erysipelas, in his paper on this medicine, he was not ignorant of its utility (*vide* his letter in the RECORD, pages 327 and 328). We have on our table Prof. Binz's contribution on quinine (quoted by him), but it furnishes no proof that Dr. Bartholow informed the profession that it is an invaluable agent in the treatment of erysipelatous inflammation. We will leave, therefore, the original record just as it stands before the profession. That is an impartial, and we have always found it a just reference. But the most notable portion of his letter is that in which he comments upon what we have said against the hypodermic use of quinine. Very justly has he foreseen that his "opinions cannot receive our approval." We do not see the faintest probability that our respective views can ever be made to harmonize. We totally despair of ever converting any one from a belief which he defends by an argument like the following, viz.: An isolated case of fatal tetanus, following the wound of the hypodermic syringe, used to introduce quinine, proves nothing. Tetanus has followed the puncture of a sewing-needle.

"According to Dr. Rogers's logic, the puncture of a needle having caused tetanus, needles should no more be used." (Vide *the* letter.)

What hope has the profession that the author of such an argument will ever recover his reason?

And again: "He" (Dr. Rogers) "applies the same logic to the other occasional accident of the hypodermic injection of quinine, the formation of abscesses. One would suppose from Dr. Rogers's statements that accidents from the internal use of quinine were unknown." (*Vide* the letter.) Has the profession any reasonable hope that the author of such a sentiment, of such a senseless deduction, will ever become a discreet and safe practitioner of our art, or that he will ever make a prudent teacher? Is it in the slightest degree probable that the physician who regards abscesses of a troublesome or dangerous character, and even tetanus induced by the hypodermic syringe, as among the *necessary* "accidents" of the therapeutic use of quinine, or who contends that *in addition to these "accidents"* the hypodermic use of the medicine is not quite as liable as any other method to be attended by the so-called casualties of medication with active agents, will ever reform into a reliable practitioner? We have no hope of this desirable consummation. He is, no doubt, sincere in his expressed belief, that "the utility and efficiency of the hypodermic method of using quinine are too well established to be set aside on the *dicta* of Dr. Rogers." (*Vide* letter.) As we have never attempted to disprove that quinine, thus administered, is both efficient and useful, this remark is quite uncalled for, and we suspect was an astute dodging of the real question at issue, viz.: *Is it not more dangerous than its advantages will compensate for?*

We believe it is; and though we have never presumed that our "*dicta*" would "set it aside," we have honestly opposed it as a system, and we think we have collected enough evidence, from the most trustworthy sources, in support of our views, both as to the danger of the practice and to its almost total needlessness, to convince most unprejudiced and sane minds that we have not so opposed it without reason. But of the author of this letter, as already said, we despair. We doubt if even a faculty committee could either convince or reclaim him. His concluding remark, in the letter under comment, is still further in proof that our despair has foundation. After quoting some most reliable authority in support of the facts we have urged upon the attention of the profession, as to the great activity and promptness of medicinal solutions when administered by the rectum, he appends the observation that the statements of these authorities "are not in accordance with generally accepted views," and, without any further inquiry as to whether these generally accepted views are correct, adds, "and will not, I am persuaded, be confirmed by those who make the trial."

It is due to the importance of the subject, however, to divulge the fact that a great number of practitioners are making the trial, and that we hope to hear the report of their results. Indeed, much evidence of professional reflection upon the subject has already reached us.

But as having a direct reference to the writings of the author of this letter, we will venture to quote a few sentences only from a note just received from Dr. Sale, of Aberdeen, Mississippi. It will be recollected that this is the gentleman who contributed the history of the fatal tetanus, caused by the wound attending a hypodermic injection of quinine, and who, out of the ten cases in which he employed the medicine in this manner, had four other cases in which he found cause to regret having done so, on account of the violent inflammation which had been the consequence. He says: "I write this note, after a careful perusal of your communication to the New York MEDICAL RECORD on the hypodermic use of quinine, to express my thanks, and my entire concurrence in your views therein expressed, with but *two exceptions*. I recognize two conditions in which the *intra-venous* method is deemed appropriate." "One of these conditions," he says, "is sometimes met with in the South and West, as the result of hyper-emetico-catharsis, before the physician sees the patient. Very great irritability of stomach and rectum in these cases may," he thinks, "render the administration of medicine by them impracticable." We would remark, however, that we have given quinine by the rectum in acute dysentery complicating miasmatic fever, with no difficulty, and most satisfactory results, by merely adding from one-sixth to one-fourth of a grain of sulphate morphine to the solution. The other exception mentioned by Dr. Sale is found, he thinks, in the *malarial coma* of the malignant form of miasmatic fever, attended by arrest of power of deglutition, and by relaxation of sphincters. As these are just the kind of cases in which we have realized the most remarkable advantage from the rectal use of quinine, we feel assured that Dr. Sale will not encounter the difficulties he anticipates.

(See our paper on Quinine, 20th vol. Trans. American Medical Association, p. 213.) "These," adds Dr. Sale, "are the only conditions in which I would use it, and, as you see, only as a *dernier-ressort*."

At about the same date, Professor Loving, of the Starling Medical College, writes us as follows: "Your paper in the RECORD, on the hypodermic use of quinine, expresses the opinion I have often uttered in regard to that mode of administering the medicine. I think I said to you, in a former letter, that this method of using

medicines should be restricted to the neutral salt solutions, like those of morphia, atropia, etc. I perfectly agree with you, that if we can get the good effects of quinine by neither stomach nor rectum, we are rarely likely to get them by the hypodermic use; and we are pretty sure to get by this mode the evil results you so well portray in your paper. Go on touching the subject again, and may success reward you." We beg to be allowed to say that there are few physicians in this or any other country whose hospital and private practice with miasmatic disease has been more extensive than has Prof. Loving's, and that we hence value his opinion on the subject in question far above that of some we might mention, who have written much more about it than he has; and we feel proud of his sympathy with, and encouragement of our efforts to save humanity from the needless pangs and dangers of the hypodermic use of quinine. Before closing we wish to say, in response to the statement of Dr. Bartholow, that he has had occasion, before the present one, to allude to our "writings but in one instance, and then in decidedly complimentary expressions," that, while we have not the satisfaction of knowing when or where that occasion was, we presume that he found reason for his approval in what we had been so fortunate as to write.

It assuredly would be very uncomplimentary to him, were we to suppose that he had complimented any labor of ours which, in the light of science and of professional common sense, was unworthy of such compliment. We do not believe he would.

Though we may fail in the contents of this note to secure his approbation, still we intend to cultivate and to disseminate such ideas as may merit, and we fondly hope may receive, both his, and the general professional approval.

STEPHEN ROGERS.

249 WEST 42d STREET.

THE HYPODERMIC INJECTION OF QUININE.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR—In your issue of August 1, 1870, there appeared a letter from Dr. Stephen Rogers, in which that gentleman dwells upon the danger attending the hypodermic use of sulphate of quinia. The doctor speaks of the physicians of the New York Hospital as having expressed opinions on the subject. I must confess that I have failed to find in the medical journals any communication touching this matter by any of the six gentlemen of the medical staff of that institution. However, on reading Dr. Rogers's paper in the Transactions of the Am. Med. Assoc. for 1869, I find that he refers to reports published by me in the *New York Medical Journal*.* It may be proper to state that these reports were in nowise *inspired* by any of the attending physicians of the New York Hospital, and that no one but myself is responsible for any opinion or statement therein put forth. There are many points in Dr. Rogers's paper which might call for criticism; but my object is simply to state certain facts and opinions expressed by men experienced in the almost daily use of hypodermic injections of quinia, bearing upon the main point at issue, viz.: the supposed danger of acid solutions used hypodermically. This is, it strikes me, a matter of importance in the whole field of hypodermic medication, and it is important to know if there be any evidence proving that a moderately acid solution thrown under the skin causes abscess, tetanus, or other grave disturbances. I may here state that not one word in the doctor's letter, or in his paper in the Trans. of the Am. Med. Assoc., 1869, indicates that he has ever given a single hypodermic injection of quinia! How far this circumstance qualifies Dr. Rogers to sit in judgment upon the question at issue, I leave to the readers of the RECORD.

A case of tetanus occurring after a hypodermic injection of quinia, related by Dr. Sale in the *New Orleans Medical Journal*, is referred to by Dr. Rogers and the *post hoc ergo propter hoc* indorsed. We are not afforded proof that no nerve was wounded in administering the injection; that no solid particles (crystal of quinia, or foreign bodies) entered the subcutaneous connective tissue; nor that the climatic conditions were unfavorable to the development of the neurosis; all points, in my opinion, worthy of investigation before deciding that the tetanus was "produced by the administration of quinia hypodermically."

The report of the Committee of the Royal Medical and Chirurgical Society (*Medico-Chirurg. Trans.*, 1867) is most unsatisfactory, and fails to meet the requirements of modern experimental physiology. The committee do advise against the use of acid, or strongly alkaline solutions; while nothing in their report appears to show that a well-made acid solution produces inflammation. The abscess which they had to treat, after an injection of quinia, was provoked by the introduction of one ounce (!) of solution into the areolar tissue. Nowhere do they refer to the necessity of carefully filtering solutions, or to peculiar care in the cleaning of the syringe. Those who first employed the method, Chasseaud, Moore, Desvignes, were unfortunately obliged to use very imperfect syringes, or even to introduce the solution of quinia through an incision: consequently the local troubles which they had to deal with cannot rightfully be brought into this inquiry.

Now for the opinion of more recent writers on the subject. Chas. Hunter (*Lancet*, 1863, vol. ii., p. 444), speaking of hypodermic injections of quinia, says: "But is there no fear of abscess or diffuse inflammation following the puncture? So frequently have I been asked the question, that I take the present opportunity to reply, No, certainly not." He then speaks of various precautions to be observed in attempting this method, and adds, *without giving any facts to support his position:* "To employ a fluid otherwise than neutral would also irritate. True, some fluids cannot be made perfectly neutral, but so nearly so, that no irritation occurs." The difference between a nearly neutral and a slightly acid fluid is rather difficult to ascertain, I imagine. An even greater authority, probably the best writer and experimenter on the entire subject of hypodermic medication, A. Eulenberg, is even more explicit in his statement.* At page 40, he states that he has never seen local inflammatory trouble follow hypodermic injections of quinia in his own practice; adding, that in the practice of a colleague, a swelling, at first painful, lasting one month, ensued after the injection of a "turbid" solution. And yet, Dr. Eulenberg's formula is so like that of the New York Hospital, that it must be startling to one who sees in dilute sulphuric acid a fertile cause of abscess, tetanus, etc. Eulenberg directs quiniæ sulph. ʒ i., acid. sulph. dil. q. s., aquæ destil. ℥ i., to be mixed and filtered. How far the q. s. in this solution differs from the ♏ 40 in that used at the New York Hospital, I leave to pharmaceutists to determine.

* On the Subcutaneous Use of Sulphate of Quinia in Cases of Malarial Neuralgia.—*New York Med. Journal*, August, 1867.
On the Treatment of Malarial Fevers by the Subcutaneous Use of the Sulphate of Quinia.—*New York Med. Journal*, Dec. 1867.

* Die Hypodermatische Injection der Arzneimittel u. s. w. Berlin, 1867.

In the New York Hospital quinia was first used hypodermically in Sept., 1866, and this "abuse" of quinia was continued until the breaking up of the institution in Feb., 1870. At first all cases treated in this way were recorded with care; but during the last two years of this period, hypodermic injections of quinia were looked upon so much as a matter of routine, that, although very frequently employed, there are but few entered in the hospital case-books. I take the present opportunity of saying, that to Dr. W. Thurman, resident physician, in 1866, is due the credit of making the formula, and of laying down many of the important rules for the safe administration of the solution. The following is the result of my search through the case-books of the four years, giving the *minimum* number of injections recorded in those books, and the number of abscesses occurring. The latter matter has been the subject of oral and written questions addressed to all the residents on duty during the four years, so that the abscess list is, I believe, absolutely correct.

W. Thurman, Res. Phys., April 1 to Dec. 1, 1866, 70 injections, 2 abscesses (both in one case).

E. C. Seguin, Res. Phys., Dec. 2, 1866, to Aug. 7, 1867, 318 injections, 4 abscesses (all in one case, and previous to Jan. 15). One patient received at least 106 injections, taking quinia as a tonic in this manner, without having a single abscess or local trouble of any sort. This case alone should decide the question of the danger of acid solutions, as the subject was extremely anæmic and feeble, and was therefore well disposed to inflammatory manifestations. It was during this period of eleven months that the six "phlegmonoid swellings" occurred, and were successfully treated.

T. Skelding, Res. Phys., August 8, 1867, to April 8, 1868, 115 injections, 1 abscess (fluid thrown into cutis proper).

J. Vanderpool, Res. Phys., April 9, 1868, to Dec. 1, 1868, 62 injections, 2 abscesses.

[Dr. V. writes me, that a very much larger number of injections were given in this period.]

A. H. Buck, Res. Phys., Dec. 2, 1868, to April 1, 1869, 4 injections, no abscess.

[Dr. B. tells me that during his service hypodermic injections of quinia were very frequently given.]

L. D. Bulkley, Res. Phys., April 2 to August 2, 1869, 2 injections recorded (many given), no abscess.

G. A. Hathaway, Res. Phys., Aug. 3, 1869, to Feb., 1870, 22 injections, no abscess.

The total number of injections recorded on the books is 593; the number of abscesses recorded and recalled is 9.

I think, moreover, that the above-named gentlemen would concur with me in estimating, that at least one thousand hypodermic injections of quinia were given at the hospital from September, 1866, to February, 1870. It is noteworthy, that *six* of the nine abscesses occurred within the first four months of the practice, and in *two cases*. The above residents, without exception, express it as their deliberate opinion, that the sulphuric acid in the solution is not *per se* a cause of local inflammatory trouble. With this view I concur; and go further, with my friend Dr. Thurman, in thinking that the acid is, by insuring perfect solution of the crystals, a source of safety. The ex-residents assign to various causes the production of the abscesses falling under their observation, such as undissolved crystals of quinia, foreign particles in the solution (dust, fungi, sealing-wax), haste in the operation, the throwing of the fluid in the cutis, and want of care in cleaning the syringe.

After offering this evidence to the readers of the Record, I feel that something should be added concerning the method of giving the solution employed at the New York Hospital. The formula for the solution was: "Take of sulphate of quinia 60 grains, dilute sulphuric acid 40 minims, distilled water 1 fluid ounce. Mix, make a solution, and filter with the greatest care." Thirty-five minims of this solution contain four grains of quinia.

(*a*) The solution was often inspected, and re-filtered when required. The hypodermic syringe was cleaned with water *always* (at least during my own term of service) before or after use. (*b*) Of course, in a hospital receiving a large number of cases of malarial disease, as did the New York Hospital, the syringe is used so much that there is little danger of rust or dust settling upon any of its parts. In private practice too much care cannot be taken in cleaning the instrument often. (*c*) The following rules for the operation, given in my first report, I believe still to be good: "A fold of skin being taken up between the thumb and forefinger of the left hand, the point of the syringe was introduced at the top of the fold, where a partial anæsthesia had been induced by the pressure; the needle being put in its full length, the solution was forced in gradually as the needle was withdrawn, so as to throw the liquid as much as possible into the track of the wound, and to cause the least possible rupture of the connective tissue. After taking out the syringe a little circular friction was generally used, with the view of assisting absorption. The slight hæmorrhage sometimes following the operation was easily controlled by finger-pressure."

Judging from experience, I unhesitatingly recommend this method of giving quinia in the following circumstances: 1st. In general hospitals, civil and military, where economy in the use of quinia is a *desideratum;* at the New York hospital no saving was effected on the whole, in the opinion of Mr. Johnson, the very capable apothecary of the hospital. This was owing to a number of causes which I cannot enter upon here, but which do not prevent me from saying that the method *may* be made economical. 2d. In private practice, in cases of congestive fever, when quinia cannot be administered by the mouth, or where rapid action is desired. I do not advocate this to the exclusion of the injection of the remedy into the rectum, as recommended by Dr. Rogers, but would remark that well-directed experiments are needed upon this point. 3d. In private and hospital practice, for the treatment of neuralgia of malarial origin, in which affection remarkable results are obtained by local injections of quinia; the drug acting in its specific manner upon the system, and locally by counter-irritation. Lastly, I may state that Dr. Lucius D. Bulkley has informed me that, while resident in the hospital, he several times observed a rapid improvement in the pulse of patients affected with partial collapse, subsequent to severe hæmoptysis, after the simultaneous injection of two, three, and even four full doses of quinia (♏xxxv) under the skin.

Yours respectfully,

E. C. Seguin.

58 West 26th Street.

THE CERTIFICATES OF DEATH FROM PHYSICIANS.

BUREAU OF RECORDS OF VITAL STATISTICS, HEALTH DEPARTMENT OF THE CITY OF NEW YORK, NO. 301 MOTT STREET.

New York, *Oct.* 7, 1870.

TO THE EDITOR OF THE MEDICAL RECORD.

Sir—For the general information of the profession I beg that you will publish the following resolution passed by the Board of Health August 23, 1870:—

"It shall be the duty of each and every practising physician in the city of New York to report in writing to the Board of Health the death of any of his patients who shall have died in said city of disease, within 24 hours thereafter, and to state in such report the specific name and type of such disease."

The object of the above resolution is to correct what has become a very serious abuse, viz: the detention of Certificates of Death for days, and in some cases weeks, by Undertakers to whom they have been entrusted, and the consequent suppression, for that period, of information essential to the proper operation of this Department.

I have been directed by the Board to report the names of all physicians neglecting to comply with the twenty-four hour regulation. The penalty for each offence is a fine of $100.

The resolution referred to has been advertised according to law in the secular press. Perhaps the publication of this note in your Journal may be of some value as a further means of information to many who might otherwise remain in ignorance of the law.

Very respectfully, your obedient servant,

CHAS. P. RUSSEL, M. D.

Register of Records.

Medical Items and News.

PROF. VON GRAEFE'S FORTUNE.—The annual income of the late Von Graefe, inherited from his father, was about $25,000, while that from his profession was estimated at $100,000.

THE FIRST INSTANCE WHERE INSURANCE HAS BEEN PAID ON THE LIFE OF A CENTENARIAN.—An English insurance company recently paid the insurance of a man who took out his policy in 1799, and died at the age of 103.

OVARIOTOMY IN A VERY YOUNG SUBJECT.—Prof. Jonon, of Nantes, not long ago removed an abdominal tumor from a girl, 12 years of age, who had been suffering eighteen months. The cyst was multilocular, and the adhesions numerous. On the forty-sixth day after the operation she was well.

A MEDICAL STATESMAN.—It is not often that we refer to international politics. The revelations of duplicity and intriguing which have just spread abroad an universal feeling of insecurity and mistrust induce us, however, to recall to memory the career as a statesman of a member of our own profession. Virchow is perhaps the most illustrious of living physicians; he has, too, the honor of having been for many years the foremost opponent of the ambitious and unprincipled schemes of Count Bismarck. At one time matters had gone so far, that rumor averred that the Count had sent him a challenge to fight a duel. For years Virchow, in his capacity as representative, was the eloquent and fearless opponent of all arbitrary exercise of power and unflinching advocate of popular institutions. The success of Bismarck's great but unprincipled schemes, in reference, first to Schleswig, and secondly to Austria, threw the constitutional party in Prussia into the background. Those who, with eyes opened by recent events, see in honest parliamentary government the only real security against the base plots of military autocrats, will now know how to appreciate the course taken by our illustrious *confrère*, and will equally admire in Virchow the genius of the pathologist and the sagacity of the patriot. It is not often permitted to the same man to display such splendid excellence in such different careers.—*British Med. Journal.*

DIAGNOSIS BETWEEN REAL AND APPARENT DEATH.—Dr. Laborde, in a paper recently read by him before the Academy of Medicine in Paris, has endeavored to show that the effect produced on a bright steel needle inserted into the body indicates whether death has or has not occurred. When life is present, he says, the needle, generally very soon, becomes more or less tarnished by oxidation; when, on the other hand, death has taken place, the needle, even at the end of half an hour or an hour, will retain its brightness. M. Laborde believes that, in the first instance, the occurrence of oxidation, with its attendant electric phenomena, indicates that death is only apparent; while, in the second, the complete absence of oxidation is a sign of real death. The communication has been referred to a committee consisting of MM. Gavarret, Béclard, and Vulpian.—*British Med. Journal.*

MEDICAL EDUCATION FOR WOMEN.—Fourteen ladies are studying at the University of Zurich, twelve of whom are in the department of medicine, and two in philosophy. One of these ladies is from Boston, two from London, one from Edinburgh, eight from Russia, one from Finland, and one from Switzerland.

STEAMBOAT AMBULANCES ON THE RHINE.—Ten steamboats are on service as floating ambulances on the Rhine, from Mannheim to Dusseldorf. The Geneva flag floats at the topmast of each. The wounded are better located in these floating hospitals than they were before; but there is a want of medical aid in them.

A SURGEON KILLED.—Among the physicians killed on the field, victims of their devotion, is M. Milliot. He was extracting a bullet from Colonel Colomieu, and had just successfully completed the operation, when he was killed on the spot.

COMPOSITION OF BONES.—At the meeting of the Academy of Sciences, August 16th, M. Wurtz presented a note by M. F. Papillon, on modifications in the immediate composition of bones, proving that the normal lime contained in the bones of animals may be partially replaced by alumina, magnesia, or strontia, by including these substances in their food.

SMALLPOX IN IRELAND.—So thoroughly is Ireland now guarded from smallpox by compulsory vaccination, that only one death from it occurred in that country during the last quarter.

PLAGUE IN SOUTH AMERICA.—A report comes from Chili to the effect that an epidemic has appeared in that republic. The first symptoms are described as those of fever, followed on the second or third day by the outbreak of gangrenous spots on the face; then ulceration supervenes, especially about the nose and mouth, which fall off in pieces. We await a confirmation of this report with some degree of interest, for, in the absence of more purely medical details, we can only say that the symptoms would apparently correspond with the disease known as plague, which, under a variety of modifications, devastated Europe during the classical and middle ages, its last appearance having taken place, if we remember aright, at Bengasi, about ten years ago.—*Lancet.*

CORNELL UNIVERSITY.—This young and flourishing University, through Prof. Goldwin Smith, is the recipent of a case of human bones from an old cemetery in England. These remains are valuable as demonstrating that our female ancestors were not necessarily of Celtic origin, whom our Saxon forefathers found in the island, as some of them are indisputably remains of female skeletons of the Saxon race.

A. "Headless Horseman."—At the battle of Wöerth it is said that at the third charge of the Cuirassiers a horse was to be seen going at full speed with a headless rider. The mutilated corpse was that of M. de la Futzun de Lacarre, Colonel of the 3rd Regiment of Cuirassiers, who had been decapitated by a cannon-ball. Most people on reading this would declare that it was a mere sensation paragraph, totally devoid of truth. Such an occurrence, however, would not by any means seem to be an impossibility.—*Lancet.*

A New Antiseptic.—The hydrated chloride of aluminium, to which Mr. John Gamgee has recently drawn the attention of medical men and of the general public, appears to be a valuable antiseptic. It is quite as potent as chloride of zinc or carbolic acid, and is at the same time non-poisonous, and devoid of unpleasant smell of every kind. These qualities will no doubt ensure its being extensively used, and at no distant date we may expect it to displace the antiseptics which are at present in vogue.

It is somewhat strange that this substance should have been so long overlooked as a possible antiseptic, and Mr. Gamgee certainly deserves credit for suggesting the utilization of it for this purpose. The reason why it has been passed over is probably to be sought in its not being a waste product in any common chemical manufacture. The anhydrous chloride of aluminium, which is manufactured in order to serve for the preparation of metallic aluminium, is far too costly on account of the troublesome nature of the process by which it is prepared—to wit, by passing chlorine at high temperatures over a mixture of aluminium and charcoal. By placing the anhydrous chloride of aluminium in water, it is of course converted into hydrated chloride.

The most economical process for the preparation of the hydrated chloride of aluminium appears to be by double decomposition between sulphate of alumina and chloride of calcium (both of which are cheap commercial products.) When solutions of these two salts are mixed together, sulphate of lime is formed and appears as a precipitate, whilst the hydrated chloride of aluminium remains dissolved.

On allowing the aqueous solution to evaporate at a very gentle heat and afterwards cooling, crystals of hydrated chloride are produced. If an attempt be made to drive off the water from the hydrated chloride by the application of heat, decomposition will take place. Hydrochloric acid is evolved under these conditions, and oxy-chloride of aluminium is formed, and, by pushing the process, alumina is obtained as the ultimate fixed product.—*Lancet.*

Tubercular Meningitis.—Dr. Vogel, in his work on Diseases of Children, denies that it is possible to prove the absence of inherited taint in this fatal disease, and, from several years of large practice in a poor district, he concludes that tuberculosis is far less common than it would be if external conditions had much influence in its production. He regards the arachnoid as the seat of tubercles in this disease. He observes that in this disease it is always to be remarked that an older, larger, yellow tubercle exists somewhere else in the body. He condemns the use of mercury in this disease.

Professor James P. White, M.D.—The faculty of the Bellevue Hospital Medical College have secured the services of Prof. White, of Buffalo, as lecturer upon Obstetrics and Diseases of Women and Children, and Clinical Midwifery, for the present session, rendered necessary by the illness of Professor George T. Elliot, M.D., the incumbent of the chair.

The Medical Times of Philadelphia.—We have received the first number of this journal, which was issued on the 1st of October. It is well printed, contains sixteen doubled-columned pages, and is to be issued semi-monthly. The number before us is an excellent one in every respect, giving an assurance that the editor, Dr. Rhodes, not only understands what he has to do, but how to do it. It contains first-class articles by Drs. S. D. Gross, Alfred Stillé, Hunter McGuire, R. Bartholow, and C. T. Hunter.

Signs of Death.—It will be remembered that a bequest has been recently made to the Academy of Medicine of Paris for the purpose of enabling the Academy to award annually a valuable prize for the best means of unfailingly demonstrating the existence of death, and thus guarding against premature sepulture. M. Bonchut has suggested that the contraction and dilatation of the pupil by calabar bean and atropine is a reliable test, and one capable of being employed without suffering or danger to the patient.—*Med. Press and Circular.*

Croup.—Dr. Vogel, of Dorpat, Russia, says that both emetics and tracheotomy are useless in croup, which in well declared cases may be set down as a fatal disease. He believes that the reason why Trousseau succeeded so often in his tracheotomy cases was because diphtheria is common in that country and that croup is often confounded with catarrhal laryngitis.

Variations in Maternal Milk.—M. Louis Sourdat has addressed to the Paris Academy of Sciences an observation on the unequal production and differing composition of the milk from two breasts of the same woman.

Having noticed the very remarkable preference manifested by the infant for the right breast of its mother—a preference shown by two previous children—and having at the same time made the remark that the right breast was much larger than the other, and gave double the quantity of milk, he thought it worth while to make examination of the milk from each. He arrived at the following conclusions:—

1. The composition of the milk produced by the two breasts, taken together, is from day to day very variable, although there be no appreciable change in the state of health. But temporary fatigue, or change of diet, or the keeping of the milk in the breasts, is sufficient to cause this difference. Thus, in analyses, the dried residue varied from 10 to 13·70 per cent. The density was also very variable. He obtained for the mean of the two breasts specific gravities varying from ·980 to 1·031.

A LECTURE ON THE EXAMINATION OF AURAL PATIENTS.

By D. B. ST. JOHN ROOSA, M.D.,

CLINICAL PROFESSOR OF DISEASES OF THE EYE AND EAR IN THE UNIVERSITY OF NEW YORK, ETC.

GENTLEMEN—It is a self-evident proposition that in order to the intelligent treatment of any disease, there must be a careful and thorough examination of the parts involved. This is certainly as true as regards the affections of the ear as of those of any other organ. In making such an examination a definite plan should be followed, even in the seemingly simple cases, until at last a large experience enables the practitioner to omit or hurry over some of the details which were necessary in the beginning of his practice.

In the examination of an aural patient, the following method is the one that I have found very useful: I usually keep a record of the cases; a plan which the young, and consequently not very busy, practitioner will find extremely valuable. The name, age, and occupation of the patient are noted. The history should then be given. This history should include a pretty full statement of the general condition, the diseases from which the patient has suffered, the number of times he has had what is called "ear ache," the medication to which he has been subjected, and so on, from his earliest recollections until the date of his coming under observation as an aural patient.

By no other means than by eliciting such a history can the practitioner get the essential knowledge for a thorough understanding of the subjective manifestations of the affection of the ear. It is very important to ascertain when the troublesome symptoms were *first* observed. Sometimes several minutes will be consumed in obtaining an answer to this question. The first reply will be, perhaps, "a few months ago," or, "a year or two." If this response be followed by the inquiry, "Before that time were your ears perfectly well?" in many instances the patient will state, "Well, no. I have had a little dulness of hearing on one side, for ten or twelve years, or for a good while" (which proves to be a number of years), or perhaps he says "there has been a little discharge from that ear, which 'didn't amount to much,' ever since I had the scarlet fever or the measles." As illustrative of this point, I may mention a case which lately came to this clinic, one which some of you remember; the patient, an old man, gave the following history:—"While sitting quietly by the fire, blood began to run from his ears, until he had lost quite an amount; he stated positively that this was the first time in all his long life that he had ever been affected with an ear trouble, and that he could imagine no cause for it." On close examination with the style of questioning above indicated, he admitted that he had suffered from a "slight running from the ears, which didn't signify, ever since he was a child." An inspection of the organs showed that both membranæ tympani were removed by ulceration, and that exuberant granulations existed, which accounted for this seemingly mysterious hemorrhage, to which the patient could assign no cause.

It is well in obtaining the history to allow the patient to tell his own story, occasionally interrupting him, as may be necessary, in order to keep him to the matter in hand. After having thus obtained as accurate a history as may be, testing the amount of hearing comes next in order. We have three means for this purpose:—

1. The tick of a watch.
2. Ordinary conversation.
3. The tuning fork.

The second of these tests, the power of hearing conversation, perhaps tells the most about a person's practical hearing power, and yet it is the one that is carried out with most difficulty. There are many persons, who can hear the tick of an ordinary watch but a short distance, say six inches, and yet are able to hear ordinary conversation with some ease; and on the other hand, there are others, who can hear the same watch twice as far, but who are utterly unable to enjoy conversation carried on in an ordinary tone. About the best test of the hearing power that we have is the one which shows the patient's capability for hearing what is said in social intercourse, at the table, in the drawing-room, and so on. Inasmuch, however, as practitioners, especially those who live in large cities or towns, have not always, or even usually, the opportunity of making such a test of their patient's hearing capabilities, and since the amount of this power, although it may be appreciated by the observer himself, cannot be made clear to one who simply reads the case, we are obliged, in recording the histories of patients, to be content with a statement as to how far an ordinary ticking watch may be heard, or words directed to the person observed, when his face is so placed that he cannot see the mouth of the speaker. This latter precaution is an essential one, since all persons with impaired hearing soon learn to watch the lips of the speaker, in order to compensate for their loss of hearing power.

In order to test the hearing by means of the watch, it should be first placed at a distance at which its ticking cannot be heard by the patient, and then gradually approached to a situation where the ticks can be accurately counted. The latter may fairly be considered as the farthest point of distinct hearing. The ear which is not being tested should be closed during the examination by the hand. It is hard to state the distance at which a watch should be heard by a healthy ear, for the simple reason that different watches may be heard at different distances, so varying is the distinctness of the tick. It may be approximately stated, however, that an ordinary ticking watch should be heard, by a person with average hearing power, at least four feet. There are, however, exceptions to this rule. For instance, I know a medical gentleman in this city, who, as tested by the ordinary transactions of professional and social life, is not at all hard of hearing, who cannot hear a watch of common tone more than six inches. Exact examination would undoubtedly show that this gentleman's hearing is defective with regard to all tones like those of a watch.

In testing the hearing power by means of a watch, it is well to remember, as Tröltsch suggests, that all watches are heard better immediately after they are wound, and also that the intensity of their sound is increased by holding them so that the surgeon's hand covers the back, or when they are held by the patient's own hand. In the two latter instances the cause of the increased clearness of the tick is, in the one case, the prevention of reflection of sonorous waves from the watch, and in the other, the conducting power of the patient's own arm as it is stretched out.

The use of a tape or other measurer, to note the number of inches at which the watch is heard, is indispensable for an accurate record of a case. The measure should not be used, however, until the distance has been ascertained without it.

When the patient cannot hear the watch at any distance from the ear, it should be laid or pressed upon the auricle, mastoid process, or forehead. Before using a watch for the purpose of testing the hearing power of diseased ears we should carefully ascertain how far it may be heard by persons whose hearing is unimpaired.

The tuning fork is of value in determining if any disease of the auditory nerve exists, and if so, whether its lesion predominate over the affection of the outer parts of the ear.

As is well known, if we close our ears, and speak, the sound of the voice seems to be confined to the head, as it were, its reflection being to a certain extent prevented by the closure of the external auditory canal. If now the auditory nerve be sound, and there be impacted wax in one auditory canal, or a thickening of the mucous membrane lining the cavity of the tympanum, the state of things will be similar to that when the external meatus is closed by the finger, or by some similar means, and the vibration of the tuning fork will be heard more distinctly by an ear thus affected than by the sound one. If both ears are equally affected, it will be, of course, more difficult to come to a conclusion. If the nerve be seriously impaired, either primarily or secondarily, by disease which has extended from the middle ear, no such marked difference will be noticed when the external meatus is closed.

Again, when the tick of a watch cannot be heard at all, if the auditory nerve be not seriously impaired, the vibrations of the tuning fork, when its handle is placed on the teeth, forehead, or mastoid process, will be distinctly heard, while if the nerve be the seat of serious lesion, these vibrations will not be at all perceived in the head. Some deaf-mutes, who were born deaf, and probably with a disease of the central apparatus, have assured me that they always felt the sound of the tuning fork passing to the region of the diaphragm or stomach, and they wou'd involuntarily place their hand there when the vibration began. The large tuning forks of the note C are to be preferred to the smaller ones.

Von Conta* of Weimar, some years since, recommended that the tuning fork be used to the exclusion of the watch, in testing the hearing distance. In his method an elastic tube is used through which the waves of sound are conducted, instead of through the uninclosed air. The number of seconds or minutes during which the gradually decreasing vibrations of the tuning fork are heard becomes the measure of the hearing power. The fork is struck upon the knee of the examiner, and then immediately placed in the outer extremity of the tube, which has been previously placed in the patient's ear. The instant he ceases to hear the vibrations he informs the surgeon by the word, "now," who has noted the time with the watch in hand when the fork was placed in the tube.

This method is certainly not without value, but the desideratum, namely, a method by which the ability to hear sounds resembling the human voice may be accurately estimated, is yet to be obtained.

In testing the visual power we have means which indicate the practical loss of sight which the patient may have suffered. It is to be hoped that the physiology of hearing may at no distant day present us one for the accurate estimation of a loss of hearing power.

The next step after noting the hearing power in the examination of our imaginary patient, is the exploration of the auditory canal and the membranæ tympani.

It is, of course, implied in this that an affection of the auricle needs no special assistance for examination.

For the purpose of examining the external auditory canal three instruments may be necessary: a pair of angular forceps, an aural speculum, and a concave mirror or reflector. The first is of use to remove any temporary obstructions which may prevent a view; the second dilates the canal; and the third throws the light into it.

According to Wilde,* Dr. Newburg, in a Memoir published at Brussels in 1827, recommended an instrument which is the origin of all the tubular ear specula now in use. It was a slender horn tube, four inches long, with a bell-shaped outer orifice. Subsequently this instrument, which was much too long, was improved by shortening it, by Dr. Ignaz Gruber, of Vienna, and generally introduced to the profession by Sir William Wilde, in 1844. Wilde's instruments have been used by myself, to the exclusion of all others, after a fair trial of the bivalvular instrument of Kramer, and the funnel-shaped one of Toynbee. It has always been an efficient instrument in my hands. A tubular instrument of some sort is usually accepted as being the best means of exposing the canal.

Those who consider that there is an advantage in a funnel-shaped instrument will find that of Josef Gruber, of Vienna, preferable to Toynbee's, because the transition from the wide orifice, which dilates the cartilaginous part of the canal to its fullest extent, to the narrower, which exposes the osseous portion, is gradual, preventing the reflection of many rays at this point.

The speculum should be made of coin silver, for ordinary use. For the purpose of applying acids or caustics, one of hard rubber, porcelain, or glass, is to be preferred.

The instrument is warmed by the hand before being used, and then inserted gently and slowly into the meatus with the right hand, and held in position by the thumb and index finger of the left, which will keep the speculum under complete control, and enable the examiner to turn it so as to successively view the different parts of the whole surface of the membrana tympani, and at the same time to thoroughly straighten the canal by pushing up the upper wall of the canal.

It is very important that the speculum be held properly, for I have seen many a student, for the want of knowledge of this simple manipulation, labor for a long time without getting any view of the membrane, while the instrument was resting on some portion of the projecting wall of the meatus.

Having thus dilated the canal, the light may be thrown into it by means of the otoscope or reflector of Von Tröltsch, which as you see is a concave mirror of about three inches in diameter, having a focal distance of about six inches. Ordinary daylight is the best source of illumination for this mirror, although sun light, lamp light, gas light, that of a candle, or the reflection from a light colored wall, may each be made available in this method of examining the outer parts of the ear. This is a very simple process, although many make a difficult one of it. If we but use the skill we acquired in our juvenile days in throwing a dazzling light upon a desired object by means of a bit of broken mirror, it will serve us in good stead here. You observe that the mirror is held very lightly in the hand, and that the light is condensed upon any desired part by a very slight movement.

It is now almost universally conceded by the profession that this method is altogether the best that has

* Archiv für Ohrenheilkunde, B. I. S. 108.

* Aural Surgery, p. 60.

yet been suggested for the examination of the membrana tympani. It has the unequivocal endorsement of such otologists as James Hinton, of London, Schwartze, of Halle, Politzer and Joseph Gruber, of Vienna. It was first introduced to the profession at large by Professor Anton Von Tröltsch, in 1855, without previous knowledge that it had been suggested by others, although Dr. Hoffman, of Westphalia, had, as it seems, previously used an ordinary shaving mirror which he had perforated, for the examination of the ear. Professor Edward Jaeger, in his work on Cataract and Cataract Operations, suggests that his ophthalmoscope may be used with the concave mirror of four inches focal distance, for the examination of the external auditory canal. I have also been informed by numerous practitioners that they have often used the ophthalmoscopic mirror for examining the ear, but in spite of all these statements and the fact that Frank,* in his work on the Ear, gives a sketch of Hoffman's method, the credit of the use of the concave mirror for the examination of the ear as certainly belongs to Von Tröltsch, as the invention of the ophthalmoscope to Heinrich Helmholtz. It is somewhat surprising, however, that after the description which Frank gives in his text-book of Hoffman's method, and the drawing which he furnishes of the mirror, no attention was paid to the subject until Tröltsch revived it, without knowing of Hoffman's apparatus.

I introduced the use of the mirror, or otoscope as it should be called, into the practice of the New York Eye and Ear Infirmary, in 1863, where it soon superseded all other methods, and whence it has been very generally adopted in the United States.

It may be safely said that the adoption of this simple method of examination has done more for the scientific and practical study of aural disease, than any previous suggestion in this department. It has placed within the hands of every practitioner a method by which he may, in a few minutes, learn to examine a membrane which not a few physicians have never seen on the living subject.

I deem it unnecessary to describe the numerous methods which preceded that of Von Tröltsch, since they are fast becoming obsolete, and their description belongs rather to the history of otology than to a practical lecture. Even the method of examination by means of the direct rays of the sun, which held out so long in the hands of some practitioners, has at last given way to the use of the mirror and ordinary daylight.

It is sometimes convenient for the examiner and the patient to sit during the examination of the membrana tympani, and sometimes both may stand, or, as I usually examine, the patient may sit in a revolving chair, while the surgeon stands. The position of the patient will not be an important matter, so long as a good illumination is thrown into the canal. A forehead band is essential in making applications to the ear, and it is often convenient at other times. I cannot see any great advantage in the various complicated and expensive bands with ball and socket joints, but I use a simple screw attachment by which the mirror is fastened to the head band.

After having heard the patient's history, and having ascertained the amount of hearing, we may proceed to the examination of the pharynx and nares, and mouths of the Eustachian tubes. Although the profession has been a long time in coming to an appreciation of the fact, it is now generally conceded that the starting point of a large percentage of aural cases is in these parts.

* Practische Anleitung zur Erkenntniss und Behandlung der Ohrenkrankheiten, S. 49

The pharynx is best examined by turning the patient's face to an open window, and holding the tongue by means of a Turck's or a simple hinge speculum. This instrument is to be preferred to others, because the hand of the examiner does not obscure the view in its use. I often, however, use a reflector and ordinary daylight for an inspection of the pharynx, and in some respects it has its advantages over a direct illumination.

Some surgeons prefer to use artificial light, in examining the pharynx as well as other parts of the body, but I must prefer ordinary daylight for all examinations, when it is possible to use it, to that from any artificial source, or to the direct rays of the sun, since it seems to me that the natural hues are thus best observed. In the evening, of course, artificial light must be used. A reflector should then be employed. It is well to have it attached to a forehead band, as in the practice of rhinoscopy or pharyngoscopy which will be immediately described, but I may defer any description of what to observe on examining the fauces and pharynx until we come to speak of pharyngeal disease.

Rhinoscopy, as a practical method of examining the posterior nares, was suggested by that distinguished man Sir William Wilde in his very valuable treatise on aural surgery, having previously been spoken of by Bozzini, in a book published in Weimar in 1807.

Professor Czermak, of Prague, following up Turck's investigations on the larynx, was the first to actually introduce rhinoscopy into anything like general use, while Dr. Semeleder, Surgeon to the Gumpendorf Hospital in Vienna, and afterwards Surgeon to the Archduke Maximilian, while in Mexico, gave us the first full account of what was to be observed by this means, with some interesting cases. Voltolini, of Breslau, has also added much to our knowledge of the value of this means of diagnosis.

It is by no means necessary that every aural patient should be examined with the so-called rhinoscope, nor will the most accomplished manipulator be able to see the mouth of the Eustachian tubes in every case; but every one who attempts to treat the disease of the organ of hearing will find his diagnosis very often facilitated by an inspection of these parts, for example, when any unusual difficulty is experienced in entering the mouth of the Eustachian tube.

For the practice of rhinoscopy we need a lamp, or other source of artificial illumination, a small mirror, a tongue spatula, and a concave mirror that may be attached to a forehead band or placed on Semeleder's spectacle frame. Any brightly burning lamp, or a good Argand gas burner, will answer as a source of illumination.

Various kinds of costly apparatus for the purpose of condensing the light have been suggested and employed. If the surgeon be not satisfied with an ordinary lamp, perhaps the apparatus of Tobold will be found the best. In some instances, although not always, an instrument for holding back the uvula is required. Various appliances have been suggested for this purpose, nooses, hooks, spatulas, and so on, for any of which a surgeon of ordinary tact will find or provide a substitute when wanted.

It is above all things requisite that the patient should be tractable, and this tractability is perhaps more common than many surgeons imagine. Those who precede all their manipulations by an appeal to their patients to be very quiet, to be sure not to stir, not to mind a little pain, &c., and who at the same time make a great show of instruments, will generally have intractable and timid patients, but he who goes quietly at work, will find few patients that will not submit

with more or less patience to all such manipulations as are required in rhinoscopy, the use of the Eustachian catheter, and the like.

The patient being seated in front of the examiner, with a good light at one side, the mouth is well opened, and the tongue held by means of the depressor mentioned above. The surgeon should be careful in placing the tongue depressor, so that he may not cause undue pressure, which will produce gagging, and prevent all further manipulations. The light is then turned upon the pharynx by the head mirror so that it is accurately focussed, when the parts will be well illuminated.

Having secured a good view of the pharynx, uvula, and tonsils, the throat mirror is to be introduced. This instrument is first warmed by holding it for an instant over the flame of the lamp, its heat is then tested by placing it on the back of the head, after which it is gently and quickly introduced with its reflecting face upwards into the space between the soft palate and cavity of the posterior pharyngeal wall.

We may now turn, as the next step in our examination of a case of supposed aural disease, to the investigation of the condition of the Eustachian tube and cavity of the tympanum.

The means of this examination may be classified as follows:

I. The Eustachian Catheter.
II. Politzer's method.
III. Valsalva's method.
IV. Eustachian Bougies.

From the date of the promulgation of the use of the Eustachian catheter by the Post-master of Versailles, Guyot, until Toynbee's time, the views of the profession as regards the use of this instrument have varied exceedingly. At one time it was almost utterly rejected by the greater number of respectable practitioners, and at another considered by them as a panacea in the treatment of aural disease. The text-books of Wilde and Toynbee, which attached very little importance to the use of the Eustachian catheter, and which bear intrinsic evidence that the authors did not choose to be very familiar with the details of the proper employment of the instrument, probably did more than anything else to cause the profession in our own country to settle down, until a few years since, into the belief that the Eustachian catheter was always a useless and sometimes a dangerous instrument. I well remember the discouraging response of a prominent American practitioner, who had then had large experience in aural disease, to my statement, at the beginning of my active professional life, that I proposed to use the Eustachian catheter in the treatment of diseases of the ear, that he was glad to say that he never had used the instrument, and this was the common sentiment among our respectable practitioners until a very recent date. In regard to the change in sentiment in this regard, I need only say, that nearly every American surgeon who now treats aural disease, attaches much importance to the use of this instrument.

It is with it for the purpose of diagnosis that we have now to speak of the Eustachian catheter.

The material of which the instrument should be made may be either alloyed silver, or hard rubber. For diagnosis the silver catheter is to be preferred; for the injection of vapors, the hard rubber instrument is the only one to be used, because the heat will very soon make it impossible for a patient to bear the metal instrument in the nostril.

In the method of introduction, we proceed as did Archibald Cleland, an English surgeon, who, after Guyot, did the most to demonstrate the utility of entering the mouth of the Eustachian tube with an instrument, and we pass the catheter through the nostril. It is very difficult to imagine how the Versailles layman succeeded in introducing an instrument into the tube, through the mouth. He certainly did not use a catheter such as we now employ, and which I now show you. It is, as you see, a delicate tube of about six inches in length, with a slight curve at its extremity. A long and flexible catheter might, it is true, be passed behind the soft palate into the mouth of the tube, and this is probably the operation which Guyot demonstrated to the Paris Academicians, and which relieved his impairment of hearing by removing mucus from about the trumpet-shaped pharyngeal extremity of the canal.

The most practicable method of introducing a curved instrument into the mouth of the tube, is the one so clearly described by William Kramer, of Berlin.*

"The patient, if an adult, should be placed upon a chair with a back somewhat higher than usual, in order that the head may be supported; children should be placed with their back against a grown-up person, or, if reliance can be placed on their steadiness, against a wall, a table, or the like. After the patient has blown his nose, in order to moisten it, the catheter being thoroughly cleansed and warmed, the surgeon forces air through it, in order to assure himself that it is permeable. The head of the patient is then fixed with the left hand; the catheter is held with the thumb and finger of the right hand close to the funnel-shaped extremity, in such a manner that the ring attached is turned downward; the beak is placed in the nasal meatus, resting upon its floor close to its septum, with the convexity upwards. From this point it is pushed backwards with a very light hand, hugging as much as possible the floor of the nostril with continual elevation of the handle, till the instrument becomes horizontal and its extremity rests against the posterior wall of the pharynx.

"As the point of the beak arrives at the posterior wall of the pharynx, the funnel-shaped end of the catheter is to be raised a little above the horizontal line, and at the same time to be lightly withdrawn; the beak then sinks and rests upon the posterior wall of the soft palate, which at that instant contracts, performs a swallowing movement, raises itself, and when assisted by a quarter turn upon its axis from within outwards, lifts the beak of the instrument into the tube. Once in position the catheter should not cause the patient any inconvenience in speaking or swallowing."

Having introduced the catheter we may force air through it into the cavity of the tympanum by means of an air-bag whose nozzle should fit accurately into the funnel-shaped extremity of the nasal instrument. Air may also be blown in from the lungs of the examiner through a slender bit of rubber tubing, the tips of which are placed in the opening of the catheter and the mouth of the examiner respectively. The use of the rubber bag or syringe is to be preferred to this method as being a more cleanly and delicate one.

After air has been forced into the middle ear in this manner, the membrana tympani should again be examined by the surgeon, to determine if it has become injected, or if it has undergone any change in position; that is to say, he should see whether the current has actually reached the cavity of the tympanum or not.

Most authorities recommend the use of an instrument like the stethoscope, which is placed in the ear of the patient while the air is being driven through the tube, and they claim to be generally able to decide as

* The Aural Surgery of the Present Day. Translated by Henry Power, New Sydenham Society, London, 1868, p. 28.

to whether the air enters by the sound communicated through the tube. I am constrained to think that it is very difficult to distinguish sounds proceeding from the pharyngeal mouth of the tube from those produced in the cavity of the tympanum, and I do not, therefore, attach that importance to the use of the stethoscope in this manner, that has been usually ascribed to it; but I rely more upon the appearances of the membrane of the tympanum after the air has been forced in, with some attention also to the sensations of the patient, as to where the air is felt, than upon the use of the so-called *otoscope*—although I would be very far from wholly rejecting its employment or from denying its value.

The otoscope consists essentially of a piece of elastic tubing with a tip on each end, designed for the ear of the patient and that of the examiner respectively. It should not be called an otoscope, but rather the diagnostic tube, as Kramer suggests. The mirror for examining the ear should be called the otoscope, just as that for examining the fundus of the eye is named the ophthalmoscope, that for the throat, the laryngoscope, and so on.

The next means of examining the condition of the Eustachian tube and cavity of the tympanum is named, from the gentleman who suggested it, Politzer's method. It is a means of diagnosis and treatment of very great value, and we owe very much to Dr. Adam Politzer, of Vienna, for this method of sending air into the middle ear.

As you very well know, in the action of swallowing, the uvula rests upon the pharyngeal wall so as to shut off the upper from the lower pharyngeal space, and you remember that persons affected with cleft palate, who cannot thus separate these spaces, are greatly inconvenienced by the passage of solids and fluids upwards to the posterior nares. It was long ago shown that the pharyngeal orifice of the Eustachian tube opened during the swallowing process. Politzer's method takes advantage of these physiological facts in the following way: The person to be examined takes a little water in the mouth, while the surgeon places an air bag, with an appropriate nozzle, into one of the nostrils, closes the other with his finger and causes the patient to swallow the water at a given signal previously agreed upon, when he forces in the air by compressing the india-rubber bag. I usually count one, two, upon which the patient swallows.

The effect of the air thus forced in upon the membrana tympani is sometimes almost wonderful. A person who has become deaf to ordinary conversation sometimes in an instant again hears the familiar tones of human conversation, and feels himself in a new world. In such a case, mucus has usually obstructed the caliber of the tube, and is driven away by the current of air, which must of necessity go against the mouths of the tube, and will usually pass on into the middle ear. The patient's own testimony will usually, although not always, be conclusive as to whether the air entered the ear. The exceptional cases are those in which the Eustachian tube and the cavity of the tympanum have become so narrowed by a hypertrophy and sclerosis of the lining mucous membrane that only a very narrow, feeble current can enter. We shall have need to dwell upon the uses of Politzer's method when we are discussing the affections of the middle ear, and I therefore content myself with this description of it while we pass on to Valsalva's method of inflating the ear.

The distinguished anatomist Valsalva, who is well known to the profession by his treatise on the ear, suggested a means of inflating the membrana tympani which has become so popular as to be used by nearly two-thirds of all the patients who come to physicians on account of their ears. It has been recommended by generations of medical men as a means of curing affections of the ear, or of determining if the Eustachian tube be open, or the drumhead broken. Universal as is its use, I regard it is as almost a useless and not an entirely safe method. It consists essentially in forcing air into the ear, after a vigorous inspiration, the mouth and nostrils being closed. You observe when I inflate my ear by this method that I make a very great use of the muscles of the chest, and just in this lies the danger to the ear. This vigorous expansion of the chest causes a congestion of the ear which is sometimes more or less permanent, and materially harms the part by increasing the flow of blood to it. There is another objection to the frequent employment of the Valsalvian method or experiment, as it is sometimes styled. It soon ceases to have its momentary effect of increasing the hearing distance, which it does by rendering the membrane of the drum tenser, and the membrane becomes relaxed and flaccid, so that I have sometimes seen the membrana tympani of patients who have been in the daily and perhaps hourly habit of forcing air into the ears, flap to and fro like a valve, on the slightest movements of the nostrils.

This latter objection, of course, applies to Politzer's method if it be very frequently practised; but as it must be done by means of an apparatus, patients are not so apt to take it into their own hands.

I do not now advise the use of the Valsalvian method in the treatment of aural disease, and as a means of diagnosis it is in most cases vastly inferior to the use of the catheter or Politzer's method.

A word about the last-named means of examining the Eustachian tube, namely bougies. Filiform catgut bougies may sometimes be used with advantage in determining if the non-entrance of air by the catheter or Politzer's method be due to a stricture, but the need for their employment occurs only in a very limited number of cases, and when they are used great care and judgment are necessary. I merely mention the subject now, promising to allude to it again in this course.

You of course understand, gentlemen, that very many cases of aural disease, for example those of the external auditory canal, will not require the exhaustive examination that has just been detailed, yet many cases *will* require a systematic and complete observation, such as I have attempted to delineate, in order to a diagnosis which shall be exact and consequently valuable. The time thus consumed is sometimes considerable, but not as great in amount as you in listening to my remarks, and seeing the manipulations, will perhaps imagine. The details occupy more in description than in execution; and their strict performance will of themselves in time make you good observers of the phenomena of disease.

Morbid Pigmentation of the Skin.—Of the many syntheses and analyses taking place in the laboratory of the body, the formation and decomposition of the several pigments are not the least interesting. Many of these pigments are easily isolated; many of them, under the spectroscope, exhibit characteristic absorption bands. Including secondary products in the series, Dr. Wm. Frank Smith, of London (*Journ. Cutaneous Medicine*), finds it easy to form from them a long chromatic scale with indigo, from the urine at one extremity, and hæmato-crystalline at the other. *Hæmato-crystalline* is the most beautiful of these, and the most important of all.

Original Communications.

ANTERO-POSTERIOR SYMMETRY, WITH SPECIAL REFERENCE TO THE MUSCLES OF THE LIMBS.

By ELLIOTT COUES, A.M., M.D., Ph.D.,

ASSISTANT SURGEON, UNITED STATES' ARMY.

ARTICLE VII.

META-CARPAL AND -TARSAL MUSCLES, CONTINUED—EXTENSORS OF THE DIGITS.

We finished, in our last, consideration of three of the four sets of muscles there indicated, and come now to the fourth. This consists, in the fore limb, of the longer and shorter "extensor" (*flexor*) *carpi radialis;* in the hind, of the *peroneus longus* and *peroneus brevis*. These are held to be respectively antitypical. From indications afforded by those lower animals in which these muscles, in each limb, are more or less blended, the inference is, that they are dismemberments of one. But if so, they have been similarly differentiated, and it is as easy to homologize them individually as collectively; though they have, in each limb, been specialized, particularly in respect of the course and termination of the tendons of those of the foot.

In the forearm, it will be observed that the outer one of the two radial wrist-muscles is the larger, and the longer, from its higher origin; that it is also the more superficial. The relative length of the two is, I believe, very constantly preserved; but in many animals where both are distinct, the 'brevior' may be the larger. In man, the tendons pass side by side over the radial aspect of the back of the wrist, to be inserted into the bases of contiguous metacarpals (2d–3d). But the insertion varies: *e.g.*, in the *Ornithorhynchus*, where the muscle is single, it sends three tendons to as many metacarpals (2d–4th). The *peroneus longus* agrees with the 'longior' of the wrist, in most respects, and although it has not a femoral origin, in some animals its origin is protracted above, by the enormously developed spoon-shaped peronecranon. The *p. brevis* is shorter and less superficial; the tendons of both run together behind the external malleolus. This latter fact makes them actually extensors of the foot, whereas, to be homologous in function with the two radial wrist-muscles, they should be flexors; and this is their morphological office. The tendon of the *p. brevis* goes to the base of the fifth metatarsal; the other takes a singular course, not only in man, but in other animals. Besides its zigzag route by double reflection around malleolus and cuboid, it wanders across the sole to the opposite side. This is evidently a teleological modification; as is, indeed, the tendon being under the foot at all, instead of on the dorsum; the purpose fulfilled is evident. The diversity of termination of the muscles, in either limb, and in different animals, is no bar to the identification just made.

There is only one other metacarpal muscle of the forearm: this is the *extensor ossis metacarpi pollicis*. It does not lie conformably with any of the foregoing; apparently making one of a small separate set that also includes the extensors of the first and second pollical internodes. The determination of these muscles with regard to their posterior correlatives offers room for discussion, if not difficulty; we will therefore examine them more closely. The metacarpal extensor of the thumb arises median (both ulnar and radial), passes obliquely, and becomes wholly radial. The extensor primi internodii arises radial; the extensor secundi internodii, ulnar. Little, therefore, can be predicated from these data. The first-named is in relation, superficially and to the inner side, with the extensor communis digitorum, and extensor of the little finger; the other two have the same general surroundings.

Now, in the foot the only metatarsal muscle not yet examined is the *peroneus tertius*. In man, it is an inconsiderable muscle, appearing like an offset from the extensor digitorum longus, and is often abortive; it lies along the outer side of the latter, and its tendon goes to the base of the fifth metatarsal. It would seem at first sight to be exactly the correlative of the extensor ossis metacarpi pollicis—the first metacarpal corresponding, it will be remembered, with the fifth metatarsal. But there is an objection to this view. The peroneus tertius, so far from being a part of the extensor longus digitorum, as some anthropotomists consider it, is perfectly distinct; and, moreover, the base of the fifth metatarsal is not its true insertion. In those animals where it is normally developed it is a true fibular muscle; its tendon passes behind the external malleolus, and runs along the outer side of the foot, to the tip of the little toe; it is then seen to be the extensor longus proprius digiti minimi pedis. Under these conditions it would seem to be the correlative of the extensor secundi internodii pollicis; or perhaps to represent this and the extensor primi internodii together; for these two are doubtless dismemberments of one morphological integer. There are reasons, however, that incline me at present to the former opinion; the extensors of the pollical internodes being apparently of the same set with the extensor indicis, if not of a part with the latter; and these may be collectively better accounted for in another way, as I show hereafter. I therefore refer the peroneus tertius to the extensor ossis metacarpi pollicis.

Discussion of these muscles has already brought us to those that act upon the very distal segments—the phalanges. Lateral movement of digits, in either extremity, is mainly effected by short muscles about their bases; flexion and extension, with which alone we have to do at present, is accomplished mainly by muscles coming down from the forearm and leg. In the simplest possible condition of the terminal segments, these consist of one functional digit; the simplest mode of moving it would be by a muscle with one tendon coming down on either aspect to the last phalanx, one to straighten or "extend," the other to bend or "flex." When the digits are multiplied, this single tendon would be divided, and we should have a corresponding number, one for each digit, on both dorsal and palmar aspects. The next change would be differentiation of the muscular bodies themselves, to increase the mobility of individual digits, and consequently the pliability of the member. There is another addition; it is a *doubling* of the flexor and extensor sets; the second set going not to terminal, but to intermediate, phalanges. These modifications may be traced step by step, from almost the simplest condition above indicated, to the most complex, in man; in which species, moreover, the muscles of the fore and hind limbs are most highly specialized. There is yet another modification; the origins of digital flexors and extensors may be run up the forearm and leg to varying extent; or may be restricted to the foot; also, a homologous muscle in one species may not supply with tendons the same digits in another species. In spite of such diversity, the correlations of the muscles of the two extremities of the same species, and the special homologies of the muscles in different species,

may be determined with some success. In the former endeavor, that now engages us, we must remember that there are two systems of both flexors and extensors of the digits; one principal or original, always going to the tips of the digits; the other secondary or duplicate, only exceptionally reaching ungual segments, generally inserted into middle internodes, or variously attached to, and furthering the action of, the primary tendons. One is generally 'long,' the other generally 'short.' One is deep or 'profound,' the other superficial or 'sublime;' an arrangement best illustrated, because most closely adhered to, in the flexor set; where the muscles are respectively signalized by being "perforating" and "perforated," and by proceeding, definitely, one to the terminal, the other to the intermediate, phalanx of a digit. We commence with the *extensors*, and with those on the inner side of the two limbs: *i.e.*, ulnar and tibial, the lateral digits of which (little finger and great toe) are antitypes.

The *extensor minimi digiti* of the hand and the *extensor proprius pollicis* of the foot are obvious homotypes. This is indicated no less by their action upon correlated digits than by their relative position higher on the limb. The former lies rather deep-seated under and between the extensor communis digitorum and the "extensor" (*flexor*) carpi ulnaris; the latter lies deeply between the extensor longus digitorum and the tibialis anticus, which we have already seen to be the homotype of the carpi ulnaris. Both proceed to ungual phalanges. This identification is plain enough. We will only add, that if these be dismemberments of the common extensor, they have been differentiated in a perfectly symmetrical manner.

Next in order toward the outer side, we find in both limbs the great extensor that divides into several tendons for as many digits. In the forearm and leg, these muscles are symmetrically disposed; they occupy the same relative position, and indeed the same actual position, as far as the different shape of the two limbs will allow. Both run the whole length of the segment; both are superficial muscles; both subdivide, at wrist and ankle respectively; the tendons of both proceed, really, to ungual phalanges; but both are also virtually inserted into other phalanges by their extensive aponeurotic expansions, and fibrous bands. There is no doubt that these muscles are correlative. The slight disparity in the number of tendons into which they divide, and in the correspondences of the individual digits they supply, appears in the light of comparative anatomy of little or no consequence.

The fact, that although these muscles reach ungual segments and are principal extensors, they are virtually inserted also into intermediate segments, and are also superficial muscles, seems to indicate that they are *analogous* to the superficial perforated flexor tendons on the opposite aspects of their respective limbs.

Deep-seated on the forearm, and there and on the wrist covered by the extensor digitorum communis, lie the special muscles of the thumb and forefinger before mentioned. The two thumb extensors, as already stated, are probably dismemberments of one. They are not constant; the extensor primi internodii is frequently or usually wanting in lower animals; and in the first step from man—in the gorilla, for instance—the extensor secundi internodii has already blended with the extensor indicis to constitute a single double-tendoned muscle. On the front of the leg there is no muscle to correspond to these, either individually or collectively. But on the dorsum of the foot there is a considerable muscle, the *extensor brevis digitorum*, that supplies the deficiency.* Its restriction to the instep, instead of its running up the leg, is exactly analogous to the similar restriction of the flexor brevis digitorum to the sole. There can be little if any doubt that these special deep-seated digital extensors of the two limbs are correlatives; but more detailed identification is difficult. This seems to arise from the fact, that the great teleological modification of the thumb and great toe makes these digits functionally correspondent, while they are morphologically opposed, so that the muscles acting upon them are obscured by specialization to a corresponding degree. The clue to more particular identification of these muscles will probably be given by correct determination of the special homology of the peroneus tertius in different animals, including that of the long peroneal extensor of the toes of the opossum, as well as of the special extensor of the little toe of the same animal. At present, I refer the human peroneus tertius to the extensor ossis metacarpi pollicis, and the extensor brevis digitorum pedis to the special extensors of the thumb and index. Still, in view of the fact that what is to all appearance the peroneus tertius in lower animals becomes the proper extensor of the little toe, it may be necessary to refer it, in man, to one or the other, or both, of the extensors of the pollical internodes, and even to include there also the extensor indicis. In such determination, however, both the extensor ossis metacarpi pollicis and the extensor brevis digitorum pedis would be left without visible correlative in the opposite limb: for certainly they do not represent each other.

NOTES ON INTERMITTENT FEVER.

By H. S. KILBOURNE, M.D.,

FORT SILL, I. T.

The management of some hundreds of intermittents in a malarious district in the South-west, in which the milder forms of intermittent principally prevail, has convinced me of the correctness of the following observations:

That there is a notable tendency in most intermittents to recurrence of the paroxysm on the seventh day from date of the last attack, and on some multiple of seven, as far as the twenty-first.

That nervous depression and indigestion, occurring in persons subject to intermittent, are exciting causes—that is to say, these conditions will precipitate an attack, when one is continually under the influence of miasma, which, without the aid of them, would not occur. I admit herein the difficulty of discrimination between the above conditions and those disorders of innervation and digestion which precede and accompany an ague. I had a case in which the disturbance that follows indulgence in the use of alcoholic liquors was almost invariably followed by an ague.

* This view is corroborated by the singular disposition of the homologous muscles in the opossum's foot. In this animal, the common long extensor of the toes comes down from the front of the leg much as in man, with the same general distribution. But on the instep there is only a remnant of muscle to represent an extensor brevis digitorum; it sends one delicate tendon to the great toe; sometimes another to the second toe. To atone for this defect, there is a large muscle, that I take to be homologous with the extensor brevis digitorum of man. It is one of the peroneal group, as the ext. brevis of man would be if prolonged up the leg in the direction of its fibres. It comes down behind the external malleolus, gains the instep, and splits into three or four tendons, that supply as many of the lesser toes.—the great toe being already provided for by the fasciculus upon the instep. The objection is, that the fasciculus upon the instep may be the whole extensor brevis digitorum, and the long peroneal extensor be consequently something else; perhaps true peroneus tertius; in which event, other identifications than those above proposed will be required.

I have another, in which the free use of cigars is often followed by a paroxysm.

That physical vigor does not prevent the invasion of malarial disorders, but it has power to resist and delay the invasion.

That various hygienic measures, such as avoidance of night air, cold bathing, and active exercise, have failed to be preventive, but that these have appeared to delay the invasion.

That quinine in small daily doses (gr. j. ad gr. v.) is not a reliable prophylactic.

That quinine is generally an efficient prophylactic when administered several hours before the expected attack, in quantities of ten grains or more.

That in some cases of chronic intermittent with malarial cachexia, quinine in large doses (℈j. ad ℈ij.) will fail to arrest the paroxysm. That in these latter cases, a course of the liq. potassæ arsenitis and iron is more efficacious than quinine.

That in a certain proportion of cases all treatment will fail and a change of climate alone will effect a cure.

The above observations lead me to the following conclusions, theoretical and practical:—First, That the specific miasmatic cause of intermittents is accumulated in the bodies of every one within its influence, until what is termed the point of saturation is reached—when an ague results. That the amount of malaria retained in the body determines the attack, and that this amount may vary with the physical condition of each individual.

That the ague is the effort of nature to eliminate the miasma.

That the miasma is a depression of the vital power, and that any agent which lowers the vitality, pari passu, lowers the point of saturation and hastens an attack.

I infer also that quinine has the power to prevent and cure an ague only when taken in quantity sufficient to produce its specific effect, *i.e.*, cinchonism.

That this power in certain cases is lost. Finally, that hygienic measures are useful in delaying the invasion of ague, but cannot be relied on as preventive when miasma is very active.

I advocate the employment of the hygienic measures indicated, and also the use of tonics and stimulants, especially iron, wine, ale, coffee, and tea, in malarious regions. I believe that malaria is especially active in the early morning and evening, and at such times should not be encountered without preparation.

An outline of the treatment pursued is as follows:—During the cold stage, a few drops of chloroform, or Hoffman's anodyne on sugar. During the hot stage, an effervescent saline laxative, in broken doses, or pulv. doveri, gr. x—the former is grateful and refreshing. During the sweating nothing is given. After the subsidence of the paroxysm, quinine, ℈ j. in a single dose, in the form most agreeable to the patient. Sponging with cool or tepid water in second and third stages. In a case of congestive remittent, when nothing was retained by the stomach or rectum, quinine gr. x et morph. sulph. gr. ⅛ was administered hypodermically with success.

Liqueur de Villatto.—M. Nélaton (*Union Med.*) recommends the subjoined modification of the liqueur de villatto as an injection to be thrown into the fistulous tracts connected with carious bone: Acetic acid, 100 parts; sulphate of copper and sulphate of zinc, of each 10 parts; acetate of lead, 5 parts. The solution requires shaking before using it, on account of the considerable precipitate.

DISLOCATION OF THE HEAD OF THE RADIUS BACKWARDS AND OUTWARDS.

By JOHN N. BEEKMAN, M.D.,

SURGEON TO THE N. Y. DISPENSARY.

John A——, age three and a half years, was brought to the Dispensary on May 3d, 1870, by his parents, who stated that a short time previous, while at play, he was thrown down by a boy, who also fell upon him; but in what position he fell they are unable to state.

Upon examination the left forearm was found slightly flexed, semi-pronated and deflected outwards, while the anterior aspect of the joint was much broader than that of the other side. The swelling was moderate, and complete supination impossible. On examining the elbow-joint, the head of the radius was distinctly felt behind and towards the outer side of the external condyle of the os brachii, the depression on its extremity being quite distinct. No fracture could be detected.

The dislocation was reduced in the following manner: Slightly flexing the forearm, and at the same time making traction upon it, pressure was made upon the head of the radius in a direction downwards and inwards with the thumb, when it slipped into its place with a distinct jerk, supination immediately taking place. The hand and arm were then bandaged, and a straight anterior splint applied. On May 10, the joint was found still quite tender, but the swelling was subsiding, and after slight passive motion had been made the splint was re-applied. On May 17, the swelling and tenderness had both diminished considerably, the splint was discontinued, and passive motion made every other day.

The joint is still somewhat stiff, but under frictions and passive motion continues to improve.

18 East 20th St., N. Y.

Progress of Medical Science.

The Febrifuge Action of Cold Water.—James S. Bailey, M.D., Albany, N. Y. (*Buffalo Med. & Surg. Journal*), asserts that cold water internally, under proper restrictions, is applicable to every stage and form of disease. If it acts otherwise, such cases are the exception, not the rule.

Water as a therapeutic may be abused—every remedy is liable to misuse—but the thoughtful physician will not attempt to ride this as a hobby to the exclusion of reason and common sense.

There is nothing in fever which acts so charmingly; it not only allays thirst, but unlocks the secretions, causing copious perspirations, reducing the temperature of the body, and equalizing the circulation in a degree which nothing else so effectively accomplishes.

The practice of causing a patient with fever to abstain from the use of water is cruel in the extreme, and very unnecessary; a full draught of cold water will not produce congestion of the stomach and bowels, but will produce the effects just described. The absorbents in fever are not so active as in health, and the water in contact with the fevered surface of the stomach soon becomes heated and is rejected, which is followed by relaxation and a determination of the blood to the surface, which is a desirable result.

The Discovery of the Arrest of Catalytic Action by Bisulphite of Soda.—In 1861, Dr. Guiseppe Polli, of Milan, accepting the zymotic theory a

true, discovered by experiments that the bisulphite of soda was quite as decided as the sulphurous acid itself in checking fermentation, and established therefrom two great facts; first, that the bisulphite of soda is carried into the circulation; and secondly, that the presence of these salts in the liquids and solids of the body retards putrefactive fermentation for a lengthened period.—*Pacific Med. & Surg. Journal.*

A NEW VESICANT.—In a recent number of the *Journal de Chimie Médicale*, M. Delpech calls attention to the defects of the ordinary preparations of cantharides; the proportion of the active agent, or cantharidin, varying, the presence of fatty or oily substances sometimes causing the absorption of a dangerous poison, and the resin or turpentine employed in the composition of the plaster being an unnecessary irritant. In place of this, he recommends the cantharidinate of potash, which is of a very stable composition, has no odor, and possesses a vesicant action in a high degree. He recommends as the best formula for the plaster: Gelatin, 2.09 parts; water, 10 parts; alcohol, 10 parts; cantharidinate of potash, 0.20; glycerine, 9.5 parts. The mass should be equally spread on thin gutta-percha, a definite quantity being present in each square inch.—*Lancet.*

TREATMENT OF OBESITY.—The *Tribune Médicale* of May 29th, 1870, mentions the case of a medical student of Paris, who, at the age of twenty-two, consulted Dr. Labat, in July, 1869, for an inconvenient accumulation of fat. Weight, 310 pounds; abdominal circumference about one yard and a half, and all the concomitant distressing symptoms. The patient was sent to Marienbad, in Bohemia, where he drank the waters, took reducing pills (with an alkaline base, to saponify the fat), had vapor baths followed by rubbing, douches, frictions with a brush moistened with vinegar of pine-cone, and wet cloths on the abdomen on going to bed. This was carried on from the 20th of July to the 31st of August—viz., 41 days. He had then lost 34 pounds (Austrian weights being heavier than French). At Paris the Marienbad waters and vapor baths were continued for a fortnight. The patient then commenced the grape treatment, both in the French capital and at Fontainebleau, with a few vapor baths. Weight on leaving off the treatment, Nov. 10th, 257 pounds; abdominal circumference about 1 yard 7 inches.

TUBERCULOSIS AND CANCER.—The correlation of these diseases has been for some time past the object of anxious thought on the part of medical men. Facts have so distinctly obtruded themselves on the attention of observers that the mere collection of cases will go far to establish a relationship between tuberculosis and cancer. Among the most intelligent physicians who have clinically studied the subject is Dr. Burdel, of Vierzon, in France. On the 17th of May last he read a paper before the Academy of Medicine of Paris, in which it is stated that the diseases have been observed in more than one hundred families, both by the author and his father, to whose practice he has succeeded. It was found that parents affected with cancer had children who presented the tubercular diathesis. Dr. Burdel's memoir is remarkable, not only for the care with which the statistics were collected, but also for the sober manner in which theorizing is attempted. The facts speak so forcibly that the profession cannot fail to be struck by them. It would be well if one of our societies would next winter appoint a committee to receive reports from medical men all over the country, respecting their experience on this important subject. —*Lancet.*

TETANUS.—Dr. David W. Yandell, of Louisville, Ky. (*The Am. Practitioner*), lays down the following conclusions in regard to tetanus:—

1st. That traumatic tetanus occurs in males in the proportion of four to one, and tends to recovery oftenest in females.

2d. That tetanus is most fatal in persons under ten years of age; that it is least fatal between ten and twenty years.

3d. That traumatic tetanus usually supervenes between four and nine days after the injury, and these cases represent the largest mortality.

4th. Recoveries from traumatic tetanus have been usually in cases in which the disease occurs subsequent to nine days after the injury.

5th. When the symptoms last fourteen days, recovery is the rule and death the exception, *apparently independent of the treatment.*

6th. Of all the forms of tetanus, that appearing in the puerperal state is the most fatal.

7th. That chloroform, up to this time, has yielded the largest percentage of cures in acute tetanus.

8th. The true test of a remedy for tetanus is its influence on the history of the disease. (*a*) Does it cure cases in which the disease has set in previous to the ninth day? (*b*) Does it fail in cases whose duration exceeds fourteen days?

9th. That no agent, tried by these tests, has yet established its claims as a true remedy for tetanus.

OZÆNA.—Trousseau's favorite injections in ozæna were: No. 1. chlorate of potash, one part; water, one hundred parts. No. 2, nitrate of silver, five parts; distilled water, one hundred parts. No. 3, sulphate of copper or zinc, five parts; distilled water, one hundred parts.—*Lectures on Clin. Medicine.*

CHLORIDE OF AMMONIUM IN HEPATITIS AND HEPATIC ABSCESS.—W. Stewart, M.D., Surg. in an English Regt. in India (*The Madras Monthly Jour. Med. Science*), states that in cases of hepatitis, where the peculiar symptoms pointing to abscess, either impending or already formed, are manifested, the *chloride of ammonium* should be administered in doses of grs. xx., morning and evening, noting carefully its effects, which are striking and remarkably regular in the order of their occurrence. Chloride of ammonium being itself a general stimulant, does away with the necessity for the employment of alcoholic stimulants in the considerable quantities otherwise required, and, unlike them, in addition to causing the absorption of pus, exercises a specific therapeutic action on the liver.

A remedy which is at once found to possess the several properties of a stimulant of the capillary circulation, general and special, which is at the same time a powerful diuretic and diaphoretic, and withal anodyne, cannot, he thinks, but exercise a remarkable influence on the processes of nutrition and absorption, secretion and excretion. Three cases are published which were cured with this remedy: the first, a case of well marked *acute hepatitis*, the second one of *suppurative hepatitis*, and the third one of *chronic hepatitis.*

SNAKE-BITE TREATED WITH POTASH AND BRANDY.—John Short, M.D., Supt.-Genl. of Vaccination, Madras Presidency (*Madras Monthly Journ. Med. Science*), relies upon liquor potassæ and brandy internally, and a hot or cold potash bath (liquor potassæ ʒ ij. to the gallon of water), in conjunction with an early ligature and scarification, in cases of bites from the venomous *cobra di capello.* In one of his published cases the liquor potassæ was given, in doses from xv. to xxx. ɱ with brandy, every 15 or 20 minutes for six hours. A

warm potash bath was occasionally resorted to. The patient recovered.

Malignant Diseases of the Uterus.—We glean from Prof. Fordyce Barker's monograph on "Some Clinical Observations on the Malignant Diseases of the Uterus" the following facts: It is, relatively, as often met with in the country as the city. There were in England from 1838 to 1842, 3,000 deaths from cancer of the uterus. In France, in the department of the Seine, from the year 1830 to 1835, there were 2,480 deaths from the same cause. From the mortuary records of New York City, there were 431 deaths from cancer of the uterus in the ten years ending Dec. 31, 1865. There were 298 deaths during the three succeeding years, and the first 9 months of 1869.

The Parisian mortality from this cause exceeded that of New York in the proportion of 413 to 79 annually in the years compared.

The African race are comparatively exempt from the disease.

His record of the comparative frequency of the forms of malignant disease is as follows: Cancer of the uterus, 487; Cauliflower excrescence, 18; Corroding ulcer, 6; Recurrent fibroid, 3.

Origin of Catarrhal Conjunctivitis.—Prof. L. Gosselin, Surgeon to L'Hôpital de la Charité, of Paris, publishes an article, on *the Origin by Contagion of Catarrhal Conjunctivitis.* (*Arch. Générales de Méd.*, Apr., 1869), in which he arrives at the conclusion that the different forms of conjunctivitis (catarrhal, purulent, and granular) are susceptible of transmission not only by contact, but by miasms emanating from diseased eyes and spreading in the atmosphere. One form of conjunctivitis may produce, in another eye, either the same, or some other form.

Syphilitic Amaurosis.—Galezowski, in a paper on *Syphilitic Amaurosis*, read before the Academie de Méd. of Paris, asserts that *retinitis pigmentosa* very frequently results from syphilitic choroiditis, and that the congenital retinitis pigmentosa is a hereditary syphilitic affection (*Arch. Gén. Méd.*, Apr. 1869, p. 487). This assertion is at variance with all authors, and, to say the least, exaggerated.

Button Scurvy.—Dr. H. S. Purdon (*Journ. of Cutaneous Medicine*), in 1868, met with a case in a Belfast lane bearing a great resemblance to *button scurvy*, which was very prevalent in Ireland during the famine years of 1847–8–9. The cutaneous disease was characterized by an eruption of isolated excrescences—best marked on the arms—presenting a convex surface somewhat resembling an ordinary button, and about the size of a farthing. This disease was called by Burgess, *Ecphyma globulus.*

The Cockleburr as a Styptic.—Dr. A. H. McFall. of Plantersville, Texas (*Med. and Surg. Reporter*), in an operation for the removal of a Minié ball from the neck, which was partly encysted and lying immediately under the bifurcation of the left carotid artery, the result of a gunshot wound of several months' standing, had his attention called by Dr. Allen, of Hempstead, Texas, to the use of the expressed juice of the *cockleburr* leaves. The hemorrhage was rather profuse for a few seconds, but was instantly and permanently suppressed on the application of the above preparation.

He has used it since in two minor operations, and believes it to be one of the very best hæmostatics, the cheapest and most easily obtained.

Mode of Preparation.—Take the fresh leaves, and, after being thoroughly pounded, put them into a strong cloth, and wring out the juice into a cup or other vessel, and apply to the wounds with a sponge.

In conclusion, he inquires whether it may not be equally efficient in *post-partum hemorrhage.*

Placental Attachment.—Rigby has found the placental formation and attachment far oftener on the left side. Lange, on the right. In 188 cases, Grenser found the placental implantation 77 times on the anterior, and 93 times on the posterior wall. Martin found the placental seat in 63 cases of recently dead puerperal women, 10 times entirely on the anterior wall, 6 times anteriorly and to the right, and 8 times anteriorly and to the left; 15 times wholly posteriorly; 5 times entirely on the right wall, and twice entirely on the left. —*Am. Jour of Obstetrics.*

Fœtal Placenta.—The fœtal portion of each cotyledon consists of branching villosities of the chorion, and these branches and branchlets are given off at every possible angle from the main trunks. The final terminations of the ramifications, be they pyriform, cylindrical, fusiform, pedunculate, or drawn out into threads, are always free and unattached.

By injecting the umbilical arteries and veins with different colored materials, and by corroding away the maternal placenta, Hyrtl has demonstrated these facts in the most wonderfully beautiful manner.— *Whittaker's Prize Essay.*

Placentæ of Multiple Births.—In 14,880 births in the Vienna Clinic, Prof. Späth (*Am. Jour. of Obstetrics*) observed twins 185 times (1: 80); 135 of these were multiparæ, 50 primiparæ. There were found in 125 cases—

Separate placentæ, with two amnions and two chorions, 49 times.

Adherent placentæ, with two amnions and two chorions, 46 times.

Adherent placentæ, with two amnions and one chorion, 28 times.

Adherent placentæ, with one amnion and one chorion, 2 times.

Fatty Degeneration of the Placenta.—The placenta, as is well known, possesses no nerves, and, according to Jossinsky, all the uterine glands in the mature placenta, both with and without epithelium, show a pretty strong fatty degeneration.—*Am. Jour. of Obstetrics.*

The Administration of Chloroform in Parturition.—When chloroform is used in parturition, beyond the stage at which it produces simple drunkenness, and indifference to pain, Rev. Samuel Haughton, M.D., D.C.L. (*The Dub. Quar. Jour. Med. Science*), affirms it is positively injurious; for it destroys the action of the voluntary abdominal muscles, which constitute the chief part of the force employed in difficult labors. Hence, the muscular tissue of the uterus is left to overcome an obstacle beyond its strength, and without the aid that nature intended to be given by the abdominal muscles. The result is that labor ceases until consciousness returns, and enables the ill-treated woman to avail herself of the apparatus of abdominal muscles provided by nature for her use.

In these remarks he confines himself altogether to the physical aspects of the use of chloroform in labor; and forbears to express an opinion as to the moral effects likely to be produced by the exhibition of an intoxicating agent, administered merely for the luxurious purpose of deadening the pain of the exercise of a purely natural physiological function.

The Frequency of Hæmatocele.—Dr. R. Olshausen

(*Am. Jour. of Obstetrics*) believes that hæmatocele is of far more frequent occurrence than is generally believed. During the last two years 769 gynæcological cases were observed in the Polyclinic of Halle, and among these 29 cases of hæmatocele, equal to 4 per cent.

Syffert mentions 66 among 1,272 patients, *i.e.*, 5 per cent.

Pyæmia.—In a communication to the Academy of Medicine of Paris, Dr. Guérin disputes the prevailing theory as to the mode of development of pyæmia, viz., the result of an absorption of decomposing secretions, or of phlebitis. He believes pyæmia is a kind of typhus, a surgical typhus, excited by miasmatic emanations.—*Med. and Surg. Reporter.*

Extract of Calabar Bean.—J. B. Enz (*The Pharmacist*) recommends the following process for preparing this extract: Reduce the bean to a moderately fine powder, and macerate in alcohol, sp. gr. .830, for ten days; then transfer the powder to a percolator, and pass through alcohol until the percolate becomes colorless. Mix the tincture obtained by maceration with the percolate, distil off the alcohol, and evaporate the residue over a water-bath to the proper consistence. The yield of extract is about two per cent.

Syrup of Ipecac.—As there has been considerable difficulty in preparing a good syrup of ipecac that will keep without deterioration, Luther E. Sale (*The Pharmacist*) sends the subjoined excellent formula:—

℞ Fluid Extract of Ipecac, f℥ xvijss; Granulated Sugar, ℥ xxxij; Water, f℥ xvj.

Pour the fluid extract of ipecac on the sugar, in a shallow evaporating vessel, and set aside in a warm place to dry; when dry, add the water, dissolve the sugar with aid of gentle heat, and strain. The syrup thus prepared will measure thirty-five fluid ounces, and will correspond in strength with the officinal. This process yields a handsome syrup.

Treatment of Iritis.—The therapeutic indications are:—1st. Removal of the causes that are still somewhat active.—2d. Keeping away all sources of injury which may maintain or even increase the inflammatory process.—3d. Diminution and limitation of the proliferation of tissue, and a reduction to the normal mean of the increased nutrition.—4th. Prevention of the possible dangers from iritic neoplastic formations.—5th. In case this latter does not succeed, the direct removal or lessening of the disturbance of function caused by them.—*Stellwag on the Eye.*

Microscopical Characters of the Blood in Relapsing Fever.—H. C. Hand, M.D., resident physician in the Philadelphia Hospital (*New York Med. Jour.*), publishes some interesting observations on the blood of relapsing fever, based on a careful study of 30 cases. The most constant and important change appears to be a granular condition of the red corpuscles, as if the coloring matter were breaking up its uniform distribution and becoming collected in patches; often this granulation is most marked around the circumference of the corpuscles, giving to many of them a false appearance of crenation, and increasing it in those which are really so.

The next most important change is crenation, which occurs both in connection with the granular condition and independently of it, and in various degrees, from a mere waviness of edge to complete deformity.

The next change to be noticed is, increase of the white corpuscles. In the only microscopical observations on this subject which he has been able to find, a report of twelve cases by Dr. Cormack and Professor Allan Thompson, in 1843, it is stated that the white corpuscles are greatly increased. In only three of his cases has it been so; but the red corpuscles in their granular condition bear no inconsiderable resemblance to white. It is possible that they may have been mistaken for such.

Dr. Cormack thought the alteration of the blood could be detected a day or two before the fever commenced. That it is so, is extremely probable; certain it is that the change occurs very early.

Indeed, he is inclined to go further, and state that by living in a contaminated atmosphere the blood becomes changed without fever necessarily following. This assertion is based on the last four cases of the table, who were resident physicians of the hospital, and, of course, living in air loaded with fever poison. Their blood appeared in almost as bad a condition as some of those suffering with the fever, although none of those examined have had more than slight indisposition. Therefore, if in any case we find these blood-changes, we should be liable to err in predicting the fever about to supervene; but, if the corpuscles are normal, he thinks we should be perfectly safe in predicting immunity from it.

In most of his cases the tendency to the formation of rouleaux was very decided, showing coagulability to be little impaired. To conclude, the fever poison alters the blood before it produces any symptoms; the alteration becomes somewhat more extensive as the disease progresses, and continues for a length of time after pyrexia has disappeared, and only debility and anæmia remain.

Skin Diseases Prevalent in New England.—Dr. Howard F. Damon, of Boston. Mass., writes that furunculus, zoster, urticaria, and erysipelas, are all far more prevalent and severe in New England than the same forms of disease as usually described by English, French, or German writers.

Cases of Diseases of the Ear.—E. L. Holmes, M.D., Prof. of Ophthalmology and Otology, Rush Med. College (*Chicago Med. Journal*), thinks it well established, that of the aggregate number of patients requiring medical aid, about one-twelfth suffer from some disease of the eye. The average proportion of patients with aural diseases is about one-fifth of the number of patients with diseases of the eye.

In his own experience, during fourteen years in private and hospital practice, the aggregate number of eye cases has been 8,982; of ear cases, 1,735. Of this number 1,076 were treated in private, and 659 in dispensary practice. He has observed that relatively a smaller number of indigent patients were affected with diseases of the ear than of the eye.

Not a single case has been observed by him, in which he was confident symptoms of inflammation were confined to the membrana tympani alone, independent of disease of the middle ear or external meatus.

Out of the above 1,735 cases, chronic inflammation, middle ear, occurred in 796 cases; perforation of memb. tympani, otorrhœa, 321 times.

A Case of Acute Yellow Atrophy of the Liver.—Dr. A. Porter, Civil Surgeon, Akola (*Madras Monthly Jour. Med. Science*), reports a case of this rare disease, which occurred during the last rainy season in a robust, healthy-looking young man, aged 22 years, of intemperate habits, a prisoner in the Akola Jail. The intense jaundice, wild delirium quickly passing into coma, and speedy termination of the disease in death, with the post-mortem appearances, sufficiently indicate, he thinks, the correctness of the diagnosis, and

this, notwithstanding the failure to detect in the liver and kidneys the pathognomonic constituents, *leucine* and *tyrosine*. Of the various causes usually assigned for this disease, malaria and intemperance were the only ones present in this case. There was no history of syphilis. The *liver* was small, flaccid, weight 29 oz., and the substance of rhubarb-yellow color, made up of fat granules and cells.

Cholera in Southern India.—The year 1866 was one of very general distribution of cholera throughout the Madras Presidency. Out of a total of 586,228 deaths in the civil population, 197,955 were due to cholera, giving a proportion of cholera mortality of rather more than 35 per cent. of the whole.

The proportion of cholera mortality in the European army was a little more than 12 per cent. of the whole; of the native army, 27 per cent. of the whole deaths.

Preparation of Pyro-Tartaric Acid.—Béchamp (*The American Chemist*) first thoroughly deprives of its water of crystallization the tartaric acid to be submitted to dry distillation; next mixes the material with previously ignited pumice-stone, and submits that mixture to dry distillation. In this way 1,600 grms. of tartaric acid yield 325 grms. of crude, but crystalline, pyro-acid, which is best purified by means of alcohol of 90 per cent.

On Glaucopyrite.—According to Dr. F. Sandberger, this mineral, newly discovered, has a specific gravity of 7.181; its formula is—

$$FeS_2 + 12 \begin{Bmatrix} Fe \\ (Co) \\ (Cu) \end{Bmatrix} \begin{Bmatrix} As_2 \\ (Sb)_2 \end{Bmatrix}.$$

It contains in 100 parts, sulphur, 2.36; arsenic, 66.90; antimony, 3.59; iron, 21.38; cobalt, 4.67; copper, 1.14.—*The Am. Chemist.*

Treatment of Snake-Bite by the Injection of Liquid Ammonia.—E. H. Hall, M.D. (*Cal. Med. Gazette*), states that Prof. Halford's treatment of snake-bite by the injection of liquid ammonia has steadily gained ground, and is now recognized by the profession in Australia as a reliable cure; and the colonists there are under great obligations to the doctor for his researches, as the world at large is to Dr. Jenner for the introduction of vaccination.

With respect to the operation, he has found from experience that the injection may be made into any vein, and not necessarily near the spot where the bite was inflicted.

The instrument used by him is lancet-pointed, similar in size to the hypodermic needle, but much stronger; with the piston packed with India-rubber to meet the inequalities of the glass tube, so as to preclude the possibility of injecting atmosphere. The ammonia employed is usually liq. am. fortiss., of the strength .882, mixed in proportion of one to three of water. The vein selected, with the superficial fascia, is seized between the finger and thumb of the left hand, a lancet pushed through immediately beneath, so as to form a basis to steady the vein against the force employed in inserting the point of the syringe, which is to be pressed in to the end of the tube, to prevent the escape of the liquid, and the piston gently pushed down until about half a drachm has been injected. A wet compress of lint is then placed over the wound and bandaged. He has had three opportunities of fairly testing this treatment, and on each occasion it was successful, and left no doubt whatever of its extraordinary efficacy.

A Remarkable Case of Spermatorrhœa: Castration.—Dr. Edward Cass, of Dresden, Ohio (*Med. & Surg. Reporter*), relates the following singular case:—A young man, sixteen years of age, shoemaker, discovered for the first time one afternoon, while busy at his work, a whitish, watery discharge from the urethra. Periodically it occurred every day while at work. His health became seriously involved. Years passed on until he was thirty years of age, when he applied to the leading surgeons of Cincinnati, who were powerless to help his condition. Cauterization of the membranous portion of the urethra was performed, and Lallemand's treatment followed strictly. Castration was performed, and the patient, with the prospect of recovery, was quite cheerful and satisfied with his emasculated condition.

A year elapsed, when the *sans-testes* patient reported that he was troubled with vigorous erections, coupled with a desire for female society. These conditions had been strangers to him all his life until now. He entertained the idea of matrimony, and had in view a young maid who he knew was pleased with him. He was told to deceive no one, but first tell of his physical deficiency. He did so, and being accepted on understanding grounds, was married. No person, for a moment, would have accused him of bringing on his abnormal condition. It is remarkable that this man who, all his previous life, was lost to virile power, should, when emasculated, have venereal propensity. All physiologists revert to sperm as the controlling and exciting cause of such animal propensities; but when sperm is absent, and especially its absence restores a lost *tone*, this is unrecorded and unaccountable.

Fragment of a Knife-Blade Lodged in Chest Twelve Years, and Finally Coughed Up.—Dr. J. F. Snyder, of Virginia, Cass co., Ill. (*Chicago Med. Examiner*), recently reported a case where a man, sixty years of age, twelve years previously in a street fight was "stabbed in the back, about the lower point of the shoulder-blade," but as the wound gave him no pain and soon healed, he had no suspicion that any part of the blade had remained embedded in his body.

The patient recently applied for treatment on account of a troublesome cough. The diagnosis suggested was *circumscribed pneumonia*. The ordinary treatment was advised, and for four weeks the case continued without change, save a gradual aggravation of all the symptoms, increased dyspnœa, and free expectoration, when one day, in a hard paroxysm of coughing, the patient threw up from the right bronchia an ounce or two of pus and a hard substance, which attracted his attention by the force with which it struck the floor. On examining the substance, it proved to be the point of a knife-blade, an inch in length, half an inch in width, and weighing half a drachm. The fragment of steel was much corroded and pitted by oxidation. During the last twelve years he had occasional twinges of pain under the right shoulder-blade, which were ascribed to rheumatism. The patient rapidly recovered his health.

The points of interest in this case are, 1st. That such a foreign body should have so long remained fastened in the bone (either the scapula or the rib) without causing necrosis or other disturbance, save occasional slight pains, attributed by the patient to rheumatism. 2dly. That supposing the knife had passed *through* the bone at once, or had penetrated the thoracic cavity, between the ribs, it failed at the time to excite severe inflammation and produce exhaustive suppuration. And 3dly. That having penetrated the substance of the lung, into the brachia, by adhesive inflammation and suppuration, it should have been so easily expelled through the *thyro-arytenoid ligaments* and the *glottis*.

YELLOW FEVER AND THE VAGARIES OF THE BOARD OF HEALTH.

FROM time immemorial it has been the fate of public functionaries to incur a larger share of public reproach than has been justly their due. To this rule our Board of Health is not, perhaps, an exception. Having, as a profession, an interest in the proper sanitary care of the community, it seems not only appropriate, but natural, that we should, when an occasion demands it, call such a board to special account for sins of omission and of commission.

We have no disposition to be censorious, but we cannot, first of all, refrain from suggesting to the gentlemen who reflect the medical opinions of the Board that obvious truth or plain inference, and not unsubstantial theories for the gratification of personal spleen, should be the basis of their official acts and declarations.

This suggestion has been evoked by the late proceedings of the Sanitary Committee of the Board. We acknowledge that our information is derived from occasional reports furnished by the morning journals, and may therefore be erroneous; but as the Board is essentially a "close corporation," and, as guardian of the public health, often unapproachable and jealous of much that is locked within its capacious bosom, we must fain satisfy our appetite with the morsels that have generously been thrown into the public crib. But to the point:—

Yellow fever appeared on Governor's Island about August 14th. The season had been remarkably propitious for its development, and it seems from the reports of the Sanitary Committee that the other concomitant circumstances for its evolution were present within the infected territory, restricted, as is frequently characteristic of such outbreaks, to a limited portion of the island. Dr. Page, the surgeon in charge of the post, failed to recognize its true character, notwithstanding its peculiar fatality. It was not until September 13th that its existence came to the knowledge of the Board from several deaths having occurred in the city "reported" by somebody as the result of "yellow fever," and found to have been contracted at Governor's Island. Who this somebody was to whose discrimination may be traced the discovery of the disease is one of the secrets of the Board. Whoever he may have been, he was immediately reproved officially for his presumption, in a report made to the Board Sept. 20th, by Dr. Morris. There it was stated most emphatically that "all the facts" had been "*thoroughly* investigated," and "post mortem examinations upon the bodies gave satisfactory evidence that *the disease was not yellow fever.*" His report closes by stating: "Various opinions have been expressed by those of the medical profession who have been conversant with the facts connected with these cases, some classifying it as malarial bilious, and others as pernicious remittent and typhoid fever. Whatever may be its special nomenclature, *the fact is established beyond doubt that it is not yellow fever*, or a disease of a contagious character." One would imagine that these unequivocal declarations of the principal executive officer of the Department, fortified by the opinions of the Sanitary Committee, should have quieted all apprehension in the Board. But it appears that Judge Bosworth's mind failed to be convinced by these statements, as he speedily afterwards despatched to Governor's Island for further investigation a gentleman familiar with the disease, but not connected with the Department. Upon his representations of the *actual* state of affairs, the Sanitary Committee deemed it advisable at once to betake themselves again to the suspected spot (only five days subsequent to a previous "careful examination of the cases" in question). The result of this new visit is embodied in their report, presented Oct. 4th. They experienced no difficulty, on this occasion, in determining the nature of the disease, although, as they modestly asserted, "up to this time its true character had not been suspected by those who had been familiar with the disease in its Southern habitats."

In this report, likewise, they did not neglect the splendid opportunity afforded them of throwing a hot shot into the camp of the enemies of their colleague—the health officer of the port—by means of the following ingenious and wholly gratuitous inference: "Respecting the origin of the disease, and the circumstances of its introduction upon Governor's Island, from all the investigations possible in this limited time, your committee cannot but come to the conclusion that its source has been from infected vessels that have been allowed to land and lie at the docks of Brooklyn, ranging from a point at the empire stores downward as far as the Hamilton Ferry, opposite to the eastern shores of Governor's Island. Any infected article thrown overboard from these vessels would, by the natural flow of the tides of this point, be washed upon the beach of Governor's Island opposite to the quarters where the fever first broke out." Truly, our distinguished health officer must have grimly laughed in his sleeve at the announcement of this conclusion, resulting from the *investigations* of his confrères. For the

same committee, in its reply to Gen. McDowell's letter of defiance, refusing to subject the post to evacuation, conflagration, and "steam-heat," quote the following in support of their views: "These buildings are spoken of by Assistant Surgeon Guild, in his report on Yellow Fever on Governor's Island in 1856 (Med. Statistics U. S. Army, 1855 to 60) as a row of old dilapidated frame tenements, occupied by soldiers' families, and familiarly known as 'Rotten Row.'" Again he says, "the only locality within the limits of this post at all suspicious of giving rise to this disease *ab initio* is that excrescence of the Island, Rotten Row. It is an old wooden shell of a building, with many inmates, and affords more filth than all the rest of the Island besides."

In the same letter the Committee arrogate to themselves the sole credit of having discovered the special character of the epidemic, in the following language: "There is abundant proof that but for those visits (*i. e.* those of the Committee of the Board) the true nature of a malignant fever that had already prevailed nearly seven weeks among the residents would not have been discovered, nor would any measures have been taken to arrest its progress."

The gentlemen of the Sanitary Committee do not hesitate afterwards to assign *contagious* qualities to this disorder, in order to impress upon the public the value of their exertions. They state in the letter alluded to: "In dealing with an epidemic like that now prevailing there (on Governor's Island), its efforts have been limited to a simple watchfulness over those persons who may escape from the island, or who, visiting the island, return to the city. All such persons have been carefully sought for throughout the city by the health inspectors, and every possible care taken to prevent any detriment to the public health by exposure to these individuals." In one fatal case we understand that the assemblage of friends at the funeral was prohibited by the Board.

With regard to the prevalence of the disease in the city, there seems to have been as much difference among the medical members of the department as there had been unanimity of opinion, in the first place, that several cases dying in the city were anything but yellow fever, and, in the second place, that they could not be anything else. Dr. Russel, the Registrar, in an official report, on Oct. 11th, stated that up to that date only *one* fatal case of yellow fever had been registered, but added, in deference probably to the convictions of his associates, and their admissions of their inability to make a diagnosis of the milder cases on Governor's Island: "There is little doubt, however, that a number of deaths from this disease have been attributed to other causes of a malignant character, and hence it is altogether reasonable to presume that a considerable proportion of cases, less typical, have recovered without recognition by their medical attendants." The ground taken by this presumption is by no means untenable, considering the great number of visitors from the city who were known to have exposed themselves to the infection during the seven weeks of unrestricted intercourse with the island, and the few who ever came within the observation of the Board. In the officially recognized cases, besides, the attending physicians had naturally, from inexperience and ignorance of their origin, been unable to arrive at a correct conclusion, and others might have attended similar cases with a similar lack of perception. The Sanitary Committee, however, could not permit so dangerous a heresy to go forth without protest, and on Oct. 18th reported that it took exception to the last clause of Dr. Russel's report on Vital Statistics regarding Yellow Fever cases occurring in the city. The Committee asserted that "there have been but nine deaths and two cases of recovery from yellow fever in the city. It has carefully inquired into all the circumstances relating to these cases and it is satisfied that the disease in each case was contracted on Governor's Island, and that there is no evidence to show that there have been any cases of sickness or death from this disease other than those enumerated above."

We do not consider it necessary to express any opinion upon the circumstances which we have reviewed. They speak for themselves; and we believe ourselves justified simply in styling them the "Vagaries of the Board of Health."

A suit for malpractice which has some interest to surgeons has just been terminated in this city. The defendant was Dr. Lewis A. Sayre of this city. The patient, a child suffering from scrofulous abscess of the hip, was brought to him by the parent, who supposed the disease to be morbus coxarius. She was informed to the contrary and the abscess was opened. The child screamed and the mother became frantic and left the office with great precipitancy. The patient was not seen again by the surgeon professionally. A foolish charge was started that the latter had punctured the hip-joint by mistake and consequently maimed the patient for life. This view was accepted by some medical men who were induced to believe the misrepresentations of the patient's friends, and the case found its way, as is usual under such circumstances, into the court. We are pleased to say, on behalf of Dr. Sayre and the profession at large, that the plaintiff failed to substantiate the charges, and was non-suited. The point, however, is, that in the course of the suit a new precedent was established. Dr. Sayre demanded that the child should be subjected to a personal examination by experts, as access to it had been denied. This application, at first strenuously resisted, was finally granted in an able decision rendered by Judge Jones of the Superior Court. He reasoned from analogous cases, such as alleged impotence or pregnancy, and traced back the origin of bills of discovery, and placed this upon the same footing. His ruling, in this instance, is one of the greatest advances in medical jurisprudence

made by the Court during half a century, and will do much in future to discover the truth and to prevent malicious attacks upon medical men. It virtually puts an end to pretended injuries and trumped-up sufferings, which disappear as soon as the trial is over and the damages secured. We congratulate the defendant as being an instrument to so desirable an end.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

STATED MEETING, OCTOBER 6, 1870.

DR. H. D. BULKLEY, President, in the Chair.

THE President announced that Dr. John G. Adams was the biographer of the late Alexander H. Stevens, M.D., LL.D.

PATHOLOGY OF PULMONARY PHTHISIS.

Dr. Wm. H. Draper then read a scientific and voluminous paper on "Pathology of Pulmonary Phthisis," of which the following is an abstract:—

It is a common observation that chemical medicine adapts itself very gradually to new discoveries in Pathology. The old principles which have guided the practitioner at the bedside, and formed the stand-point from which he has watched the origin and measured the progress of disease, are abandoned always with reluctance, and every innovation must make its way against time-honored prejudices by the force of positive demonstration or the results of irrefutable experience. That the time has come to modify seriously the doctrines of Laennec and Louis in regard to the pathology of pulmonary phthisis, is the conviction of many who have been forced, by observation and experience in the light of modern pathology, to seek a more satisfactory explanation of many of the phenomena in the chemical history of consumption, as well as of many of the changes in its morbid anatomy.

It was doubtless this conviction that induced our worthy president to suggest this subject to the Academy for discussion; and while I recognize with him the interest and great practical importance of the questions it involves, I cannot but express my regret that the opening of the discussion had not fallen to some more experienced member of the Academy. You may perhaps be reconciled to the choice of the president by regarding me as a sort of junior counsel put forward to state the case for the advocates of the new views, while you wait patiently for the arguments of the older and more learned counsellors to whom we look for judicial opinions upon vexed questions.

Before entering upon an explanation of the modern views of the pathology of pulmonary phthisis, it will be important to the proper development of the subject to review the opinions of the earlier authorities on this disease, especially as these opinions are still widely held, and by many stoutly defended.

The word *phthisis* was originally applied to any form of disease that was accompanied by rapid wasting of the body, and its first limitation was its restriction to the diseases of the respiratory organs which were associated with emaciation.

The term *tubercle* was formerly applied to any little nodule or tumor, whatever its nature or location; and though still in common use in its liberal sense, its specific application to the peculiar variety of nodosities developed in pulmonary phthisis dates from the beginning of the present century.

. . . . . .

In the early discussions as to the nature of tubercle, the great source of confusion lay in the vicious use of the word tubercle, Laennec and his followers insisting that the transparent miliary granulation and the yellow infiltrated masses were only different forms of the same specific substance, and that the infiltrations could not be the result of inflammation because the granulations were not; while Broussais and his school, accepting the same broad signification which Laennec had given to tubercle, claimed that the yellow cheesy masses were certainly inflammatory, and therefore the granulations must be. Laennec protested that whenever evidences of inflammation existed in pulmonary phthisis they were secondary to the irritation produced by the deposit of tubercle, and hence he denied that acute or chronic pneumonia, bronchitis, or pleurisy, ever terminated in tuberculosis.

. . . . . .

Virchow first recognized the fact that the miliary granulation found in tuberculous subjects, either alone or in connection with inflammatory products, is a new formation of cellular nature, and, to quote his own description, "generally has its origin, like all other new formations, in connective tissue; and which, when it has reached a certain degree of development, constitutes a minute knot within this tissue. This knot, when it is at the surface, projects in the form of a little protuberance, and consists throughout its whole mass of small uni-or multinuclear cells." What especially characterizes this formation is the fact that it is extremely rich in nuclei, so that, when it is examined as it lies imbedded in the tissue which invests it, at the first glance there seems to be scarcely anything else than nuclei. But upon isolating the constituents of the mass, either very small cells, with one nucleus, are found, or larger cells, containing from 12 to 24 small nuclei. This structure, which in its development is comparatively more nearly related to pus, inasmuch as it has the smallest nuclei and relatively the smallest cells, is distinguished from all the more highly organized forms of cancer, cancroid and sarcoma, by the circumstance that these contain large, voluminous corpuscles with highly developed nuclei and nucleoli. Tubercle, on the contrary, is always a pitiful production—a new formation, from its very outset miserable. In its earliest stages, according to Virchow, these granulations are traversed by blood-vessels; but after a time by the pressure of the innumerable cells, the vessels are obliterated, and the process of degeneration begins in the centre, as indicated by a yellow spot. This is the commencement of the cheesy metamorphosis.

These observations of Virchow first established clear and defined ideas as to the nature of the tubercle, so far as its histological elements were concerned. They restricted the true tubercle to the miliary granulation, the true, essential anatomical element of tuberculosis. They differentiated this neoplasm from the crude tubercles and grey and yellow infiltrations, with which it had previously been confounded, and so led the way to a more rational and satisfactory explanation of the pathology of pulmonary phthisis.

In regard to the precise location of the tuberculous deposits, recent investigations have defined with more precision the exact seat of the true tubercle, and show that it is commonly developed in the adventitia, or the laminæ of connective tissue immediately surrounding the blood-vessels. According to Herard and Cornil, the miliary tubercles in the lungs develop themselves in the connective tissue which constitutes the walls of the lobules, and especially around the blood-vessels and capillaries which surround the bronchi. As the mass

enlarges through the active proliferation of nuclei and cells, it projects into the alveoli and encroaches upon the tunica of the finer bronchi, and so produces the appearance of having been developed within the bronchus or air vesicle. Another effect of the rapid proliferation is to compress the blood-vessels around which they form, and finally obliterating them, to prepare the way for the degeneration of the granulation and the destructive ulceration of the surrounding tissue.

. . . . . .

It would be a profitless task to review the many vague hypotheses which have been proposed from time to time to explain the origin of tubercle. It must be confessed that we are not made much wiser when we are told by Rokitansky, that "tubercle is in the broadest sense an exudate of solidified protein substances (albumen and fibrin)," etc., etc. Nor is it plain that we have solved the mystery of tuberculosis when we say with Simon that tubercle is that unorganizable deposit which occurs in various organs of the body, under the influence of a peculiar constitutional state which we call the scrofulous diathesis.

After recounting the experiments that have been made within the past few years in the *artificial production of tubercle by inoculation*, by Jenner, Villemin, Andrew Clark, Burdon, Sanderson, Wilson Fox, Waldenburg, and others, Dr. Draper sums up the subjoined conclusions which the facts developed justify:—

1st. That tubercle is anatomically a neoplasm, and like all heterologous tissues, has a physiological type. That the physiological type of tubercle is the lymphatic tissue.

2d. That the typical tubercle is the miliary granulation, and that the so-called crude and yellow infiltrated forms are examples of the degenerative stage or cheesy transformation, to which not only tubercle, but all heterologous growths and inflammatory products are liable.

3d. That the seat of tubercle is in the connective tissue, especially in the adventitia of the blood-vessels, in the walls of the lymphatic vessels, and the parenchyma of the lymphatic glands.

4th. That tubercle is not a specific morbid product, in the sense in which the syphilitic virus is, inasmuch as it may be produced by the inoculation of a variety of substances of animal, vegetable, and mineral origin, and that the only specificness which it exhibits is an inherited or acquired proclivity, on the part of the individual subject to it, to the development of the neoplasm, as the result of the absorption by the blood-vessels or lymphatics of such morbid products as it has been demonstrated will produce tuberculosis by inoculation in animals.

. . . . . .

It must be confessed, we think, that the advances in pathological anatomy tend to illustrate and confirm the doctrines first enunciated by Broussais—the demonstration of the true nature of caseous deposits, that they were something very different from tubercle, and nothing more nor less than progressive metamorphosis to which tubercle in common with other heterologous and inflammatory products was liable, proved that pulmonary phthisis was not necessarily tubercular. This then is the first, and perhaps practically most important, modification produced in the generally accepted pathology of pulmonary phthisis by the more intelligent views of the nature of tubercle, for which we are indebted to microscopical research.

. . . . . .

Niemeyer truly says, in the opening of his lectures on phthisis, that "no doctrine in the whole field of pathology is in such urgent need of reform as that of pulmonary phthisis," and for the reason that clinical medicine is for the most part still based on the theories of Laennec, that tubercle is the starting point of every case of phthisis, and that all the condensation and destructive processes are due either to the accumulation and softening of this substance, or to the secondary inflammation which they excite.

Now that the source of error and confusion is removed, and the true tubercle is distinguished from the false, it is time to recognize the fact which Broussais, Andral, Cruveilhier, Addison and others insisted upon —that phthisis is often a purely pulmonic process, having its foundation in pneumonia and bronchial catarrh and hemorrhage.

Laennec thought tubercle was a specific product: the experiments on animals have shown that it is not specific, inasmuch as it may be produced by the inoculation of a great variety of substances. Laennec thought that tuberculosis was a primary affection: the history of the tuberculization of animals goes to show that it is a secondary process.

The idea that tubercle is the effect of a certain so-called blood crasis was distinctly promulgated by Dittrich. His theory was that all diseases had a tendency to disturb the balance between repair and waste, and that whenever the waste was in excess, the products were accumulated in the blood, and contaminated it; that the accumulation of fibrin in the blood was the most important and serious of these contaminations, and that one of the secondary diseases to which it led was tuberculosis—so he explained the sequence of tuberculosis after the acute or chronic diseases of the lungs and other organs.

Buhl's theory of tuberculosis, based upon a series of post-mortem examinations of persons dying of pulmonary phthisis, published in 1857, is more specific, and especially interesting in view of the apparent confirmation it receives from the experiments on animals. Buhl divides cases of pulmonary consumption into three varieties: 1. *Acute miliary tuberculosis.* 2. *Acute infiltration.* 3. *Chronic tuberculosis.*

This author sums up the following facts as proofs of the resorptive origin of miliary tuberculosis:

1st. "The almost constant presence in tuberculous lungs of yellow tubercles and cavities."

2d. "These masses are not encapsulated, and the cavities are not everywhere bounded by thick fibroid connective tissue; therefore, resorption can easily occur."

3d. "The largest collection of miliary tubercle is at first soft, gray, and situated in the immediate neighborhood of the infecting mass."

4th. The circumstance of "the eccentric progress by the formation of new miliary tubercles, in such a way that the oldest and largest tubercles which have already become yellow or farther changed by shrinking or pigmentation are nearest the infecting mass, while the youngest, smallest, soft, gray, thickly-sown tubercles are farthest from it."

5th. The fact of "the possible occurrence of gray and at the same time miliary tubercles in almost every parenchymatous organ and serous membrane, even if there were only one resorptive mass in the body."

6th. "The clinical and anatomical appearance of an infectious disease, and especially the anatomical appearance of a specific infectious disease."

7th. "The situation of the single gray miliary granulations in those tissue-intervals which belong to the lymphatic vessels."

Buhl's *second* variety of pulmonary consumption, or acute infiltration, he compares with diphtheria, and calls it "lobular diphtheritic pneumonia." This pro-

cess, he believes, has nothing in common with miliary tuberculosis, but may give rise to it. His *third* variety or chronic tuberculosis, he thinks may arise from the second, but may also arise from an inflammatory or croupous capillary bronchitis.

Buhl believes in the specific nature of the tubercle virus, and applies the term tubercle, as Laennec did, to the various forms of new morbid products found in the lungs of phthisical patients. He farther argues the specific nature of the tubercle virus by stating his belief that it is transmitted in the human ovum and semen, in this way explaining the hereditary nature of the disease.

The almost invariable coincidence of miliary tubercles with caseous masses has also been insisted upon by C. Hoffman. He found these caseous masses not only in the lung, but in the urino-genital organs, in lymphatic glands, and in the products of suppurative peritonitis. Hofmann does not accept Buhl's idea of a specific tubercle virus in these masses, reasoning that their origin is too diverse, and that their common quality of giving rise to miliary granulations must be due rather to some common physical peculiarity.

Niemeyer, in accepting Buhl's theory of the dependence of miliary tuberculosis upon the presence of caseous masses, is guarded in his statement as to the precise nature of this association. He inclines to the view that the tubercular granulations are not due to an infection of the blood by a tubercle virus, but rather to a local influence, perhaps, acting through the lymphatic vessels.

In answer to the argument in favor of tuberculosis being a general disease, that the granulations are sometimes found extensively diffused through the parenchymatous organs and on serous membranes, he replies that the territories of granulations may be due to numerous foci of resorption. Thus he believes the tubercle of the peritoneum may very often be traced to caseous ulcerations of the intestine, just as those in the pleura or in the lung may arise from a neighboring caseous mass.

. . . . . .

We have thus considered the theory of tuberculosis as a resorptive disease, and as having its origin in caseous nodules; it remains for us in conclusion to consider the conditions under which caseous masses are liable to be produced.

Niemeyer, in his monograph on "Pulmonary Phthisis," states that "all forms of pneumonia lead, though not with the same frequency, to caseous infiltration, and the formation of cavities in the lungs; and that in cases having this termination, the danger of tubercular complication is exactly the same, whether the caseous products and the cavities are the result of a croupal or catarrhal pneumonia, and whether the latter has had an acute origin or a chronic development."

This statement requires some explanation. By croupous pneumonia, Niemeyer means the ordinary lobar pneumonia—the acute, primary disease, in which he says the exudations are analogous to those of croup; and by catarrhal pneumonia he signifies the lobular pneumonia—the sub-acute, and generally consecutive disease, which is commonly disseminated through both lungs, and is secondary to acute bronchitis, or the bronchial catarrhs that complicate eruptive fevers, hooping-cough, and influenza.

. . . . . .

The rapidity with which caseous infiltration of the lung takes place as the result of the pneumonic processes varies considerably, and is due probably, as Niemeyer states, to the degree of distension which the alveoli suffer as a consequence of the cell proliferation. If they are suddenly and intensely infarcted, the pressure exerted by the cells upon each other and upon the surrounding blood-vessels induces a rapid necrosis and the formation of cavities. This rapid infiltration and consequent softening constitute the pathological conditions of the form of phthisis commonly described as "galloping consumption."

When the accumulation of cells is more gradual, the lobular condensations undergo a slower atrophy, and may finally liquefy and be absorbed, or the organic matters may be absorbed and a carbaceous concretion be left behind. While these changes are going on, an active proliferation usually occurs in the surrounding connective tissue. As this new tissue shrinks, the neighboring alveoli are obliterated, and the volume of the lung diminishes. This is followed by one or both of two inevitable effects—a sinking in of the walls of the chest, and a distension of the bronchi, the latter constituting the oblong or round caverns which are so characteristic of chronic phthisis.

What has been said in regard to the formation of caseous masses in the lungs, and their consequences, embraces a description of the sole pathological changes in many cases of pulmonary phthisis, and according to the present views of the nature of true tubercle it must be admitted that such cases are not examples of tuberculous phthisis. The changes, however, that we have described as the consequences of pneumonic inflammation are often complicated with the presence of the true tuberculous granulations, and the relation of these to the caseous infiltrations is the question about which pathologists have differed from the time of Laennec and Broussais to the present. Are the caseous masses and cavities secondary to the eruption of miliary granulations, or is the eruption of miliary granulations secondary to the formation of the caseous masses? In the possession of data necessary to the decision of this question, it must be admitted that the modern pathologists have the advantage of the disciples of Laennec.

Laennec's theory of the identity of isolated and infiltrated tubercle was based upon their common tendency to cheesy transformation. The doctrine of the diversity of the miliary granulation and caseous masses is based upon the morphological distinctions revealed by the microscope. Laennec's theory, that the primary and unique anatomical element in all forms of consumption is tubercle, was a corollary, from the confounding of essentially different substances under the name of tubercle.

. . . . . .

The doctrine of the modern pathologists, that the miliary granulation is the sequence and result of the resorption of caseous masses, seems to be justified by the experimental genesis of miliary tubercle in the inoculation of the lower animals.

The relation of tuberculosis of the lungs to caseous lymphatic glands, and to caseous masses of diverse origin in other parts of the body, is established not only by experiments upon animals, but also by clinical observation. Another point of great interest upon which modern pathology has reversed the doctrine of Laennec and his school, is the relation of hæmoptysis to pulmonary tuberculosis. Laennec contended that it was always the sequence of tuberculous deposit; while modern observation makes it the precursor of caseous masses, and through them of tuberculosis.

In conclusion, we have only to say that the great interest which has of late years been awakened in the pathology of pulmonary phthisis, is more than justified by the great practical importance of the results already obtained. If caseous masses are often the sequence of "neglected or ill-treated catarrhs," especially in the

feeble and ill-nourished, then certainly we have reason to expect that the frequency of this sequence may be diminished by natural treatment; and if tuberculosis is not a specific disease, but a secondary accident, the result of a resorption of corpuscular elements from the detritus of caseous masses, then there is at least ground for the hope that the ravages of this dread disease may be measurably controlled by an intelligent prophylaxis.

The President, in stating that he was personally much pleased with the preceding paper, said that Dr. Austin Flint would read a paper at the next meeting "On Recent Views of Tuberculosis."

The announcement was also made that the discussion on both papers would follow the remarks of Dr. Flint.

On motion, the Academy adjourned.

NEW YORK PATHOLOGICAL SOCIETY.

STATED MEETING, SEPTEMBER 9, 1870.

DR. J. C. HUTCHISON, President, in the Chair.

FORMATION OF BONE IN THE EYE.

DR. H. KNAPP presented to the Society some specimens of bony growths within the eyeball, and remarked as follows:—Last year I showed to this society an eye in which an osseous capsule invested the whole inner surface of the choroid, ceasing abruptly at the beginning of the ciliary processes, continuing, however, at this point, into a false membrane which stretched transversely across the anterior part of the vitreous body about 1''' behind the lens. Since recent researches have shown that the capillary layer of the choroid does not extend over the ciliary body, I thought that ossification, being an active process requiring much nutritive material, was dependent on the capillary layer of the choroid. My friend, Dr. Althof of this city, afterwards informed me, to my surprise, that he had found ossification in the anterior part of the eye-ball and not in the posterior. He was so obliging as to give me the specimen for examination, which proved really highly interesting, and he allowed me to present it here. The choroid was found healthy. The retina detached. From the region of the ora serrata, an ossified plate extended across the vitreous. It lay behind the unchanged ciliary body. The lens was united to its membranous centre, drawn backward, shrunk, and partially calcified. I examined this specimen very carefully with the microscope, besides the fragments of two other specimens which Dr. Althof also was kind enough to place in my hands, and which are here before you. They contained thick shells of osteoid and osseous tissue on the inner surface of the choroid. Calcification existed in the anterior parts of the globe, and was also present in the interspaces of the bony shell.—Dr. Knapp illustrated the pathological conditions of the three specimens by elaborate drawings of microscopic preparations, and added that, by these investigations and the aid of the literature on the subject, he arrived at some remarkable conclusions:—

Formation of bone in the eye is the consequence and final stage of a plastic inflammation of the capillary layer of the choroid. Its seat is the inner surface of the choroid and the anterior part of the vitreous humor, behind the ciliary body and the crystalline. The diagnosis of ossification within the eye may be based upon the unyielding and hard condition of the posterior part of the globe, terminating about two lines behind the cornea, while the anterior region is soft. Calcification frequently accompanies ossification. Since ossification does not involve the outer choroidal layers, the ciliary muscle, and the iris, it, in itself, is not to be dreaded as a cause of sympathetic ophthalmia. The latter will result from chronic irido-cyclitis as a complication of ossific choroiditis.

STATED MEETING, SEPTEMBER 28, 1870.

DR. J. C. HUTCHISON, President, in the Chair.

OSTEO-MALACIA OF TARSUS, ETC.

DR. FINNELL presented a specimen of osteo-malacia of the lower extremity, removed from a female patient of St. Vincent's Hospital, who was suffering from tuberculous disease. She had disease of the ankle-joint for the past two years; but lately her sufferings became so intolerable that she determined to have the limb removed. When she entered the hospital she was suffering from all the usual symptoms of tuberculous disease of the lungs, save cough. In consultation the physicians were opposed to the operation, on the ground of the lung trouble, but the surgeons were of an opposite opinion. The operation was accordingly performed on the 27th, in the hope that the general condition of the patient might be improved. The specimen was sawn through longitudinally, showing the bones of the tarsus to be nothing more than softened, spongy masses, with pus infiltrated everywhere.

A DRESSING FOR STUMPS.

In referring to the dressing in this case he took occasion to say that he never used adhesive straps, but in their stead strips of lint soaked in a mixture composed of dilute carbolic acid, one ounce; prepared chalk, an ounce; and sweet oil, eight ounces. This was also the dressing employed in the case of amputation reported at the last meeting, and at the end of thirteen days after, when they were removed, the parts were found to be healing kindly. He preferred the lint in strips, on account of its ease of application and of removal.

During the operation an artery in the spongy tissue of the tibia bled so freely that it was necessary to plug the opening with a tapered lucifer-match and ligature attached.

DR. ROGERS had been in the habit of applying dry dressings to stumps, enveloping them, for instance, in a soft towel. He did not believe that carbolic acid was of much use in promoting the healing process in such cases.

DR. FINNELL thought that there might be danger in the ligatures adhering to the towel when the latter was removed.

DR. ROGERS remarked that there was always moisture enough from the discharges to prevent this.

DR. HUTCHISON stated that he had always succeeded in arresting hemorrhage from bone by the application of persulphate of iron, afterwards crowding the coagulum thus formed into the canal. In regard to the dressing of stumps he further remarked that he was in the habit of using none whatever, preferring to keep the parts freely exposed to the air. When it was necessary to nicely coapt wounds, he had been in the habit of painting over the edges with flexible collodion, containing from five to ten per cent. of carbolic acid. He had seen larger surfaces heal by the first intention after this application than by any other means. The paint is renewed every third day.

DR. HART had found great difficulty in preventing a peeling of this coating in warm weather.

DR. HUTCHISON.—When the collodion was good there was no danger of peeling off in warm weather.

DR. KNAPP presented two specimens of osseous de-

generation of the choroid in corroboration of the views presented at the last meeting.

DEGENERATION OF OVUM.

Dr. Van Geison exhibited an ovum discharged by a woman aged thirty-two, the mother of two children, the youngest of which, twenty months old, had been weaned six months. For three weeks past the patient had quite severe and persistent menorrhagia, ending with the appearance of the womb contents. From the persistency of the prominent symptom the existence of polypus uteri was conjectured, although no very thorough examination was made to confirm it. The ovum, which appeared to be six weeks old, had a remarkably dense covering, due, as the exhibitor believed, to some interstitial deposit in the membranes, more especially as the surface of the amnion was made very uneven by projecting nodules.

Dr. Rogers believed that the density of the membranes was due to a simple exfoliation of the chorion, amnion, and placental decidua.

Dr. Chamberlain called attention to a small point of commencing ossification in the temporal bones.

COLLAPSE OT LUNG-DIFFICULTIES IN THE DIAGNOSIS OF EMPYEMA PARACENTESIS THORACIS.

Dr. Lewis Smith presented two specimens of collapse of the lung. The first was removed from the body of an infant twelve days old, which was found in the morning lying dead beside its mother, the result of being "overlaid." The thoracic walls were somewhat compressed, the blood was unusually dark, and both lungs were nearly completely collapsed. In connection with the case he recalled five similar ones. He had been informed by the coroners that smothering was not infrequent among young infants of the poorer families, where crowding seemed to be a necessity.

The second specimen was of more interest on account of the history of the case to which it belonged. The little one was one year and eight months old at the time of its death. It had good health until the age of six months, when it commenced ailing. The physician who was in attendance upon the case failed to recognize any signs of lung trouble, leaving it presumable that the disease was latent. The infant, when eight months old, was brought to Dr. Smith. There were then no prominent symptoms to direct attention to the chest, being only a slight cough, and slight acceleration of the pulse, and respiration. The chest was, however, carefully examined for the purpose, in the hope that it might result in an explanation for the progressive emaciation. There was extreme dulness over every part of the right lung, but no marked inequality as to measurement compared with the other side. There was also broncho-vesicular respiration, but no bronchophony was noted; the diagnosis of suppurative phlebitis was made, and the operation of paracentesis advised. The mother was, however, requested to get the opinion of a distinguished physician and surgeon. That gentleman, to the surprise of Dr. Smith, stated by note that he thought the case to be one of interstitial pneumonia; that he had recognized the existence of bronchophony, and that consequently the operation was unwarrantable. On corresponding with him, he expressed the conviction that it would not even be prudent to make use of an exploring needle, and suggested that a third person examine the case. This advice was followed with the result of another decision against empyema and for interstitial pneumonia. Being thus over ruled, the patient was simply kept on the sustaining treatment during the remaining four months of its life.

At the autopsy all the organs save the right lung were healthy. This right lung was flattened and compressed by a thick fibrinous exudation upon its surface, while the chest cavity contained from eight to ten ounces of partially absorbed or thickened pus.

Remarking upon the points of interest in the case, he stated that the lungs of young infants in this condition were more apt to be compressed than the ribs were to be expanded. This explained the reason why during the last four months there was no difference in the measurements of the two sides. Again, the conduction of the liquid effusion was oftentimes so perfect, that the best auscultators could be deceived by the great proximity of the sounds to the ear.

He had seven similar cases within a year and a half, in four of which the operation was performed, followed by recovery; and in three, including the present one, it was not done on account of difficulty in diagnosis.

In answer to a question from Dr. Markoe, he stated the instrument used was an ordinary trocar, the introduction of which was prepared by an incision a little below the angle of the scapula. He also made the statement, in answer to the same gentleman, that there was no need to fear the entrance of air into the wound under the circumstances of the operation, and that he consequently was inclined to leave it open.

Dr. Watts asked if the temperature had been taken in the last case.

Dr. Smith replied that it had not been taken by the thermometer.

Dr. Markoe asked the age of the youngest patient with empyema.

Dr. Smith. The youngest that I can now recall was between two and three months. It is almost a rule that in young foundlings the pleuritis is suppurative.

Dr. Markoe had a case last summer, upon which he operated, that was only six weeks old.

Dr. Van Geison referred to a case which he saw in consultation, and in which the rational symptoms and autopsical lesions were precisely similar to those in Dr. Smith's patient. No physical signs could be made out, as the child would keep up a persistent crying whenever an examination was attempted.

Dr. Buck detailed the history of a specimen of fracture of the cervix femoris wholly within the capsule. He had come across it accidentally in the dead-house of Bellevue Hospital. There was no previous history of the case, and he regretted his inability to present the specimen.

Dr. J. C. Hutchison presented a specimen of epithelioma of the penis, which was removed from a negro sailor at the Brooklyn City Hospital, in May last. The patient, 52 years of age, entered the hospital for a suspected venereal disease. His prepuce was thickened and could not be retracted. A hardened surface could be felt beneath the foreskin, at the corona glandis, about the size of a nickel penny, which was entirely painless. There were no enlarged lymphatic glands. A few days after his admission a free hemorrhage took place through the perpetual opening, and he at once slit up the prepuce, and, exposing the ulcer, removed a small piece for microscopic examination. It was found to be epithelial cancer. The organ was amputated about one inch behind the corona, in the following manner:—An assistant encircled the organ at its root with the thumb and forefinger so as to compress the vessels, and the organ was excised at the point above indicated with a small amputating knife; there was no hemorrhage, and the vessels were closed by torsion. The mucous membrane of the urethra was then split into four quarters to the extent of two lines, and each part stitched

to the skin, so as to insure a free opening at the orifice after the healing of the wound. He had a satisfactory recovery, the orifice of the urethra being quite patulous.

Dr. Hutchison also presented three urinary calculi, weighing in the aggregate three ounces five drachms and twenty-eight grains, removed from a man 66 years old on the 10th of May last. The patient entered the Brooklyn City Hospital June 3d, 1870, presenting all the rational symptoms of stone in the bladder, from which he said he had suffered for two years. He had previously been troubled with indigestion. He was very feeble, had no appetite, and his sleep was disturbed by the necessity for evacuating the bladder frequently. His urine was ammoniacal, contained an abundance of pus and mucus, but no casts, and no more albumen than would be accounted for by the presence of the pus. An examination with the sound revealed a large stone in the bladder. No effort was made, on account of the patient's prostrate condition, to ascertain whether more than one calculus was present.

With the hope of improving his condition, preparatory to an operation, he was treated with appropriate tonics, anodynes, and generous diet, with rest. At the end of a week he had not improved, and his sufferings were so great, that Dr. H. removed the three large calculi by bi-lateral lithotomy—Professor A. C. Post's instrument being used for the operation. He bore the anæsthetic (ether) badly, and two hours after the operation he had a marked rigor. An examination of the wound showed that no urinary infiltration had taken place. On the following day he became comatose, pulse very frequent, profuse perspiration. The urine was discharged through the wound for twenty-four hours, and subsequently partly through the urethra and partly through the wound. He died on the fifth day, probably from uræmic poisoning. It was impossible to obtain a *post-mortem* examination.

NEW YORK MEDICAL JOURNAL ASSOCIATION.

Stated Reunion, October 7, 1870.

Dr. Isaac E. Taylor, President, in the Chair.

Dr. J. Lewis Smith read a paper, which we shall publish in full in a future number, on the *Symptoms and Diagnosis of Tuberculosis in Infancy and Childhood*, in continuation of the paper on the Ætiology and Anatomical Characters of the same affection, which we have already published.

Dr Dewees stated that he had been having constructed an apparatus for the generation of pure ozone, which he proposed soon to exhibit to the Association. He believed that ozone would prove of great therapeutic value in those affections where oxygen has been found of service, its greater activity enabling us to get the desired effect with a comparatively small quantity of gas.

The Librarian acknowledged the receipt of several donations to the library, for which votes of thanks were passed.

The following Order of the Board of Direction was announced:

The members of the Association will be furnished by the Librarian with Members' Cards of Admission to the Reunions and the Reading-Room, which will be necessary for admission on and after November first.

The meeting adjourned.

Stated Reunion, October 14, 1870.

Dr. Isaac E. Taylor, President, in the Chair.

SYPHILIS OF THE NERVOUS SYSTEM.

Dr. E. L. Keyes read portions of an extended and important paper upon this subject, based upon the clinical observation of thirty-four cases. It appears in full in the current number of the *New York Medical Journal*. We have space only for the summary of its conclusions:

1st. That nervous symptoms depending upon syphilis may arise within the first few weeks after contraction of an infecting chancre, or at any period later during the life of the individual.

2d. That it is presumable, from the study of published autopsies, that the earlier a nervous symptom (paralytic or otherwise) occurs, the less likely is there to be any material lesion which an autopsy can reveal; and that in a given case there exists no constancy of relation between the nature, the situation and the severity of the lesion, and the nature, situation and severity of the nervous symptom to which that lesion may give rise.

3d. That cerebral congestion is probably the pathology of many of the earlier nervous syphilitic symptoms.

4th. That syphilitic hemiplegia occurs, as a rule, without loss of consciousness even when the attack is sudden, but that the paralysis usually comes on gradually, the patient being under forty years of age and having had fixed constant headache for some time before the attack.

5th. That mydriasis existing alone or with other nervous symptoms, without positive disease of the eye, is presumptive evidence of syphilis.

6th. That paralyses of single muscles or sets of muscles are frequently syphilitic.

7th. That syphilitic paraplegia generally comes on gradually, often without any local symptom to call the patient's attention to the injured portion of the cord, and that it is rarely complete. That the bladder almost always suffers more or less, and calls for special local treatment. That paraplegia may be developed as a symptom of inherited syphilis.

8th. That syphilitic epilepsy usually occurs after thirty in patients who have not had epilepsy in early life. That headache is liable to precede the attacks. That the convulsions occur often many in quick succession, the intermission between the series of attacks being comparatively long; but that, during this period, headache or other nervous symptoms exist and become aggravated, contrary to what obtains in idiopathic epilepsy. That syphilitic epilepsy is liable to be associated with or followed by some form of paralysis.

9th. That aphasia is often associated with the intellectual disturbances caused by syphilis.

10th. That loss of memory is a common nervous symptom of syphilis, as are also all forms of mental disturbance, from mild hallucinations and illusions up to actual insanity, and all these without any necessary accompanying paralysis.

11th. That inordinate emotional expressions are often associated with the mental weakness caused by syphilis.

12th. That care must be taken to distinguish certain symptoms caused by gout from the same symptoms owing their origin to syphilis.

13th. That the prognosis is better, as a rule, for nervous symptoms caused by syphilis than for the same symptoms depending on a lesion equal in extent caused by another malady of the nervous centres; but that, after

the arrest of the disease, an indelible impression is often left upon the nerve tissue, which manifests itself by impaired function, and which treatment cannot overcome.

14th. That the iodide of potassium pushed rapidly to toleration, unless the symptoms subside before that point is reached, is the main outline of treatment. That mercury used at the same time or alternated with the iodide of potassium is often of great value in protracted or inveterate cases, and that tonics, change of air and surroundings, frequently influence the effect of treatment in a marked degree, and may become essentials to success.

DR. F. R. STURGIS, referring to a statement that syphilitic epilepsy had never been observed to occur within less than a year from the time of infection, said that he had seen a case, in the practice of Dr. Bumstead, where a young man, twenty-three years of age, had been attacked with epilepsy within six months after the initial chancre. The history of the patient was gathered from his friends, and, so far as could be learned, he had never before had epileptiform seizures.

DR. A. C. POST had examined, at his clinic the day before, an infant of twelve months, suffering from chronic hydrocephalus, and bearing undoubted evidences of syphilis. Hydrocephalus had not been mentioned as a result of this infection.

DR. R. F. WEIR had been glad to hear the rule so distinctly stated, to push the iodide of potassium rapidly to the point of toleration. He had been forcibly impressed with its importance by the case of a patient to whom he had, at one time, been giving three hundred and eighty grains a day. A woman of about forty had evanescent hemiplegia following syphilitic primary lesion. As this symptom passed off, in the course of forty-eight hours, there was developed that of a firm band about the waist, and also some trouble with the bladder. Under the use of the iodide she became convalescent, and went into the country. Some two months later she had a second evanescent attack of hemiplegia, upon the opposite side, and again the difficulty with micturition, and the distressing sensation of the girdle around the waist. She had recourse to the iodide, in saturated solution (an ounce of the salt to a fluid-ounce of water), and wrote that when she reached the dose of five hundred and seventy drops in the twenty-four hours the girdle vanished, the functions of the bladder were restored, and she felt herself a well woman. As a drop of the solution contains but about two-thirds of a grain of the salt, she was then taking three hundred and eighty grains a day.

DR. BULKLEY'S experience corroborated the statement that syphilitic hemiplegia occurs without loss of consciousness. He had also seen one case of acute syphilitic mania, like those related. In the treatment by mercurials he decidedly preferred the protiodide to the biniodide.

DR. W. H. DRAPER would refer to one point in a case, related in the paper, which had come under his own observation. He had frequently examined the patient's urine, finding nothing abnormal except, of course, the constant presence of iodide of potassium. But on one occasion he discovered large numbers of hyaline casts, especially of the smaller tubuli; they were more abundant than he had ever before seen in any case, though the urine was not albuminous. This caused him some anxiety, suggesting the question whether, in giving these large doses of iodide of potassium, we do not run the risk of laying the foundation of chronic Bright's disease. He had since often examined this patient's urine and had not again found casts; and the man was now in the enjoyment of robust health. Dr. Van Buren, to whom he had mentioned the subject, had never seen casts in the urine of patients taking the iodide. The question was an important one, as probably the greater part of the salt finds its exit in the urine, and it would seem hardly possible to keep up so great a degree of diuresis for a long time, without producing so much congestion of the kidney as to give rise to renal lesion. The speaker continued:—

Another case came under my observation about six months ago, sent to me by Dr. Tilden Brown, under whose care he had been for the six months previous, having been admitted to the Bloomingdale Asylum for symptoms of dementia. He was sent to me for excessive diuresis. I found him passing nine pints of urine in the twenty-four hours, with an average specific gravity of 1005. He was much emaciated, with dry skin, dry mouth, constipation of bowels, and marked physical exhaustion, as well as mental prostration, though from the latter he had somewhat recovered. He had hardly entered my office when he was obliged to lie down on the lounge, and it was with great difficulty that he could give me his history. At first I had no suspicion of syphilis, and treated the case with valerian, according to the suggestion of Trousseau. It produced little effect upon the polyuria. After seeing him two or three times I inquired if he had ever had any venereal disease. He said that, four years before going to the Bloomingdale Asylum, he had had a sore pronounced by Dr. Sayre to be a chancre. I inferred also, from his statements, that he had been treated with mercury. He had had multiple adenitis; and the sore had healed in five or six weeks under the medicine given him. About six months after the primary sore healed, he had a pustular eruption on the back and in the scalp. He had never had rheumatism. Thinking it possible that the diuresis might depend upon the existence of an intracranial syphilitic lesion, I determined to put the patient upon the use of increasing doses of iodide of potassium. I began with ten-grain doses, and the improvement in the patient's general condition was astonishingly rapid; he gained strength and spirits so fast as to amaze himself as well as his wife, who always accompanied him. The effect upon the urine was not so marked at first, but in the course of two months was quite decided. It had then diminished in quanity from nine pints to five or six, and attained in one instance the specific gravity of 1010. The man had meanwhile gained flesh, color, physical strength, and nervous energy. I increased the dose of the iodide to twenty grains, and continued it for three or four months longer. It is now a month since I have seen the patient.

This case interested me greatly, as suggesting the possibility of an intracranial lesion so located as to give rise to that irritation which we know will produce diabetes, either of the sweet or of the insipid form. For, although there is not, so far as I know, any observation of diabetes produced by syphilitic lesion of the brain, yet we know that experiment has demonstrated that irritation of the floor of the fourth ventricle, of the optic thalami, of the crura cerebri, or of certain portions of the spinal cord, will give rise to diabetes, sweet or insipid. We know, too, that tumors located in this region will also give rise to it; and it has been shown that in certain cases of hemiplegia dependent upon apoplectic clots diabetes occasionally results. Thus it appears to me not at all improbable that a syphilitic meningitis or gummy tumor may be so situated as to give origin to this symptom. With regard to this case I do not know that this conjecture of mine is correct, but it seems quite possible that it may be so. At any

rate, taking into consideration the cerebral symptoms for which the patient was under the care of Dr. Brown, and the diabetic symptoms for which he came under my care, and comparing the case with the instances of insanity from syphilis reported by Dr. Keyes, it becomes one of remarkable interest.

Dr. Keyes had found casts in the urine of but one of his patients while taking the iodide of potassium. He was taking the dose of eighty-seven and a half grains three times a day, when he became affected with slight nausea; and the urine exhibited hyaline casts, though very few of them, and traces of albumen; no blood. The doctor had known the patient for a couple of years before, and occasionally examined his urine, finding neither casts nor albumen. There seemed to be no cause for their appearance except the medicine, and the question had arisen whether it was justly chargeable to that. The patient went into the country, dropping one of the three doses a day and continuing the other two. The albumen and the casts gradually disappeared, and did not return.

The President said that, about twenty years ago, the question of the proper dose of the iodide of potassium was brought prominently before some of the London medical societies, and the conclusion reached that two-grain doses, long continued, were less harmful and more permanently efficacious than the larger ones.

Dr. C. C. Lee had, within two years past, had under his observation, at Charity Hospital, three cases of Bright's disease in syphilitic patients, who were given large doses of the iodide of potassium. In each of these cases, when the iodide had been taken for a week or ten days, the number of casts in the urine was materially increased, as was also the proportion of albumen. In each case he had been led to believe that the increased irritation of the kidneys was caused by the salt; which was, nevertheless, continued as long as the syphilitic symptoms remained prominent. The casts were chiefly hyaline, though in one case there were a few fatty casts, and in another a few granular ones. These last had existed previously to giving the iodide, and he did not know that they were specially increased by it.

Dr. M. H. Henry spoke of the great difference in the doses of iodide of potassium as given in England and in this country, and was convinced that our experience justified the more heroic treatment. He alluded to a frequent action of the drug in diminishing or completely dispelling the paralysis (mydriasis, ptosis, etc.) attendant on cerebral affections of syphilitic origin, while having, for a long time, no perceptible effect upon the patient's mental condition. In illustration of these points he related a case of extraordinary interest, the report of which we withhold by request, as the patient is still under treatment, and the doctor intends to report the case in full when complete.

Dr. Draper stated, in reply to a question, that in the case of dementia and diabetes which he had detailed there was no paralysis.

The President had, in several cases of syphilitic hemiplegia, given small doses of bromide of potassium in conjunction with mercury, and the results had been favorable. He thought it well to give mercurials in connection with the iodide of potassium, as it had been pretty well established in this city that these, especially the bichloride, tend to prevent the development of Bright's disease.

Dr. F. P. Foster inquired whether any of the gentlemen had seen examples of the syphilitic analgesia lately described by Fournier. He had had one case in dispensary practice. A woman whom he had treated or syphilitic iritis sent for him some months later, and he found her with slight impairment of muscular power in the right lower extremity, and very considerable impairment of sensation in the same limb. He could find nothing pointing to any lesion of the spinal cord.

Dr. R. W. Taylor had, since about the first of January, when his attention was drawn to the subject, carefully sought for this symptom in fully fifty cases of secondary syphilis in women, and had yet to find the first instance.

Dr. Keyes had been on the look-out for it, but without success.

The meeting adjourned.

Stated Reunion, October 21, 1870.

Dr. Isaac E. Taylor, President, in the Chair.

THE PROGRESS OF RELAPSING FEVER.

Dr. Elisha Harris, after a brief reference to former epidemics of relapsing fever, gave a more particular account of the progress of the disease as it has appeared in Great Britain and in this country within the past two years. He then endeavored to trace its course through the other countries of Europe and in some parts of Asia, back as far as the year 1864, though the accounts obtainable were not such as to form an unbroken chain. His researches concerning its outbreak in this city last year had been quite exhaustive, and had led to some interesting results regarding its spread from certain foci, its period of incubation, etc. He was preparing a full statement, with details of names, dates, and localities, for publication in the official report of the Health Board. In response to a question as to what were the characteristic features of the disease, he gave an account of his own sufferings in an attack which had come on just nine days after exposure, with a suddenness reminding him of his former experience of yellow fever.

STRUMOUS INGUINAL ADENITIS.

Dr. Jerome C. Smith presented a patient, thirty-two years of age, with great swelling of the glands of both groins, some of those on the left side especially having attained an enormous size. Doubtless from their interference with circulation, the scrotum had become œdematous, and was at least four or five times as large as normal; and the œdema was beginning to extend to the penis. There was nothing but scrofula to account for the glandular enlargement. The patient came of a highly scrofulous stock; his mother had suffered from strumous affections all her life, and his brothers and sisters were nearly all subject to them in one form or other. He himself showed the scars of old strumous abscesses; and about four years ago his health had rapidly failed under well-defined symptoms of pulmonary phthisis—great emaciation, night sweats, etc., and slight hæmoptysis. He had got considerably better, when, last January, the inguinal glands began to swell. He came under the speaker's observation in June; since then his general condition had much improved, and he had gained twenty-five pounds. But, in spite of local and internal treatment, the glandular swelling had persisted, being only slightly diminished, and the œdema was getting worse.

The meeting adjourned.

The Chemical Analysis of 184 Cases of Stone.—Of the 184 stones removed by Sir Henry Thompson, by the operation of lithotrity, 122 were uric acid and the urates; 16 were mixed; 40 were phosphatic; 4 oxalate of lime; 1 cystic oxide; and 1 pure phosphate of lime.

Medical Items and News.

New York Medical and Surgical Society.—At a stated meeting on the 8th inst., Dr. Adams announced the decease of Thaddeus M. Halsted, M.D., as having occurred during the summer recess, and among other remarks stated, that Dr. H. had been an active member of the Society for more than twenty-five years. Drs. Adams and Buck having been, on motion, appointed to prepare a minute in connection with this event, recommended that the following resolution be entered upon the minutes, and that a copy thereof be transmitted to the family of the deceased:—

Resolved, That the N. Y. Medical and Surgical Society enter upon their records the recent death of Thaddeus M. Halsted, M.D., for a long series of years an active and valued member of the Society. In discharging this melancholy duty, your committee cannot do justice to their own feelings, nor to the memory of the departed, without bearing testimony to the loss which this Society has sustained in the removal of one so beloved as a man, so greatly respected as an honorable and successful practitioner, and so sincerely devoted to the interests of this Society. Ever kind and genial in his spirit and intercourse, highly conservative in his views and influence, in his official trusts diligent and self-sacrificing, an honored member of an honorable profession, he has left a void in our number which is deeply lamented.

We desire, also, to express our sympathy with the bereaved relations of the departed in their deep affliction, and we recommend that (in accordance with our usage) one of our member be appointed to prepare a memoir of the life and character of the deceased.

Resolved, That these proceedings be published in the Medical Journals of this city.

Oct. 22d, 1870. John G. Adams, M.D.
Gurdon Buck, M.D.

The Opening of the Medical Colleges of New York City.—The opening exercises of the University Medical College, and College of Physicians and Surgeons, took place on Monday evening, October 3, 1870. Prof. Charles A. Budd delivered the opening address at the former Institution, and Prof. Thomas M. Markoe at the latter College.

On Wednesday evening, October 12, 1870, Prof. Frank H. Hamilton delivered the introductory address at the Bellevue Hospital Medical College. Prof. James P. White, of Buffalo, who gives the course on obstetrics this year, at this College, was called out, and made a few congratulatory remarks.

All of these institutions are in a flourishing condition, and their halls filled with students, representing every State in the Union, and the Canadas.

New York State Inebriate Asylum.—Dr. Daniel E. Dodge has charge now of this Institution, and Dr. Willard Parker is President of the Board of Trustees.

American Association for the Advancement of Science.—This Association held an interesting series of meetings at Troy, N. Y., commencing August 17th, and adjourning August 24, 1870, to the third Wednesday of August, 1870, meeting in Indianapolis, Indiana. Officers for 1871: Prof. Asa Gray, of Cambridge, *President;* Dr. Geo. F. Barker, of New Haven, *Vice-President;* F. W. Putnam, of Salem, *General Secretary;* W. O. Vaux, of Philadelphia, *Treasurer*. The meeting for 1872 was appointed for San Francisco. Two hundred members registered their names upon the books of the Treasurer. One hundred and forty-three scientific papers were presented at the Troy meeting.

New York Medico-Legal Society.—The Annual Meeting of the New York Medico-Legal Society was held at the College of Physicians and Surgeons, October 13th, 1870. The following officers were elected for the ensuing year:—Dr. Stephen Rogers, *President;* Jacob Shrady, Esq., *First Vice-President;* Dr. J. J. O'Dea, *Second Vice-President;* Dr. Kemp, *Assistant Recording Secretary;* Dr. Jean F. Chauveau, *Corresponding Secretary;* Dr. Thomas S. Bahan, *Treasurer;* William Shrady, Esq., *Librarian;* Dr. Stephen Clarke, *Curator. Trustees*:—Dr. J. C. Peters, Dr. Thomas C. Finnell, Dr. Wooster Beach, Elbridge T. Gerry, Esq., Francis Tillon, Esq., and Jacob F. Miller. The Society now numbers nearly two hundred members.

New Hampshire Asylum for the Insane.—The twenty-ninth annual report of the Trustees has been published, and from it the following facts are extracted: Nearly twenty-eight years have elapsed since the New Hampshire Asylum commenced its career at Concord. During this period 2,804 patients have been inmates and received treatment; 1,144 of these—about 41 per cent.—have been restored to mental soundness. 367 patients have been under treatment the past year, and there are now in the institution 253. Of the number admitted in 1869, 190 were men, and 177 were women.

The total daily average for the year was 249—$123\frac{1}{10}$ men, and $125\frac{9}{10}$ women. Of those discharged (91), 37 had recovered—22 men and 15 women; 34 were imprisoned—18 men and 16 women. The ratio of recoveries was very low, being only a fraction over 28 per cent. Twelve men and 11 women died. Of those admitted in 1869, 32 were between the ages of 20 and 30 years; 28 between 30 and 40 years; 30 between 40 and 50 years; under 15 years, 1. There were 26 farmers, and 41 of household occupations. Active mania was developed in 54; mild or chronic mania, in 34; insanity with epilepsy in 10; melancholia in 13, and dementia in 8 patients.

The medical officers are as follows: J. O. Bancroft, M.D., *Superintendent and Physician;* J. P. Brown, M.D., *Assistant Physician;* and Wm. H. Ruddick, M.D., *2d Assistant.*

Our Climate not Growing Colder.—At the meeting of the American Association for the Advancement of Science, held at Troy, N. Y., August 17, 1870, Prof. O. W. Morris, of the Cooper Union, New York City, read a paper on the temperature of this city for twenty-five years, which proved that the popular and prevalent impression that our climate is growing colder is totally untrue.—*American Chemist.*

The Compass Plant.—Prof. Hill (*Am. Chemist*) corroborates the fact that the edges of the leaf of the wild sun-flower—compass plant—of the western prairies, do lie north and south.

The Source of Petroleum.—Prof. Hunt (*Am. Chemist*) proves petroleum to be indigenous to certain limestones. The oil is found generally in bands or patches, with strata above and below containing no oil. The oil is hermetically sealed in the pores of the limestone, and escapes in lines of disturbance. Heat is required for the separation of the oil. Near Chicago is true limestone of the Niagara formation, containing more oil than Pennsylvania has produced for ten years. The oil, however, is not obtainable, as it does not form in pools.

Prof. Wöhler.—The 70th anniversary of the birthday of this renowned German chemist occurred on the 31st of July. He has had more American students in his laboratory than any other European professor.

THE CLIMATE OF NASSAU.—Nassau has not only been proved to be superior to all other localities as a *Sanitarium* in the New World, but superior, also, to Madeira itself. Madeira is decidedly more healthy than Nassau, from the 1st of June to the 1st of November, when the thermometer in the former island stands at an average of 71° 60′; while in the latter it averages 85° of Fahrenheit. And Surgeon General Bagot, of the British Army, very properly remarks, that no person seeking health should ever find himself in Nassau from the middle of June to the middle of October. The unhealthiness of the island in summer is conceded, but from the 1st of November to the 1st of June, *there is not, in all probability, any spot on the face of the earth* so desirable for persons suffering from Pulmonary complaints. And *Nassau is only four days' sail from New York;* the steamer landing passengers on their way to Havanna. Nassau is situated in lat. 25° 05′ North, and longitude 77° 20′ West. Madeira is in latitude 31° North. The climate of the two places, as indicated by a long series of thermometrical observations, is as follows:—

Madeira.....	Winter,	63° 50′	Spring,	64° 45′
Nassau.....	do.	70° 67′	do.	77° 67′
New York...	do.	30° 12′	do.	52° 06′

Now, you and I know, that when in winter the temperature of our houses gets down to 65°, we increase our fires; and consequently we know too, that to constitute a climate the mean or average of which is 63° the thermometer must, most of the time, be below 60°, consequently fires become a necessity; and the outdoor atmosphere is not one which an invalid afflicted with disease of the lungs may safely breathe. The remedy in all lung diseases is exercise in the open air, constantly inhaling an atmosphere of 70° or upwards; and the mean of the winter temperature in Nassau being 70° 67′, and of the spring 77° 67′, both dry with perfectly cloudless skies, there appears to be no doubt that from November to May, New Providence is without a rival as a great *Sanitarium*.

Frost has never visited Nassau—the coldest day known during the past twenty-one years of careful registration (with one exception not verified) being 64°; and the warmest, from November to May, 82°— a variation of only eighteen degrees between the coldest and the warmest day, during the period that invalids would naturally visit the Island for health. And the greatest difference in the thermometer ever recorded between October and June is only twenty degrees.

It follows, then, that there is on earth no such other place, as regards climate between October and June, as Nassau. The rain-fall during the winter and spring is as follows, viz.:—

November, 2.8; December, 2.4; January, 2.4; February, 2.4; March, 4.5; April, 2.4.

The mean height of the barometer for a series of years is ascertained to be exactly 30 inches, and the average humidity of the climate is 73.3.

During the months of March and April we had only five falls of rain, usually of only two or three hours' duration, or less; and once, raining about six hours continuously. During those two months we had rain previous to 10 P.M. but once; and both day and night the heavens were cloudless.—*Extract from Letters by Gen. J. Watson Webb.*

THE BRITISH MEDICAL JOURNAL. — Dr. Jonathan Hutchinson has resigned the editorship of the *British Medical Journal.*

A WOMAN-DOCTOR'S PRACTICE.—Mrs. Hannah E. Longshore, M.D., of Philadelphia, enjoys a lucrative practice, realizing an income of $10,000 per annum.

THE BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.—The Fortieth meeting of this honorable Society was held in Liverpool, Sept. 14, under the presidency of Prof. Huxley, F.R.S., etc.

THE BLOOMFIELD GAS WELL.—Prof. Lattimer, of Rochester University (*Am. Chemist*), has made a careful photometric test of the gas, and reports an illuminating power of fourteen candles. The supply is estimated to be ten million cubic feet per day. This is more than the daily consumption of gas in New York city. Prof. Henry Wurtz estimates the daily flow of gas to be about 400,000 cubic feet. By the removal of the carbonic acid in the gas by the use of dry lime, it is possible the illuminating power of this gas may be improved. It is proposed to supply the city of Rochester with gas from this source.

For a full description and analysis of the gas from this spring, see the *American Journal of Science* for May.

A CELEBRATED LITHIA WELL IN ENGLAND.—Redruth, in Cornwall, is the most remarkable salt and lithia well in England. It issues from a depth of 230 fathoms. The composition of the water is as follows:

Chloride of Potassium,	grs. 14.84
" " Lithium,	" 26.05
" " Sodium,	" 363.61
" " Magnesium,	" 8.86
" " Calcium,	" 215.17
Sulphate of Lime,	" 12.27
Silicic acid,	" 3.65
Total,	644.45

This well yields nearly 900 lbs. of lithia in 24 hours, being four times as much as the strongest well of it hitherto known.

THE FACE OF THE LATE PROFESSOR VON GRAEFE.—It is said the face of this renowned ophthalmologist so closely resembled one of the extant portraits of our Saviour, that he was known among some of the less reverent of his countrymen by the cognomen of Christus—a fact which sufficiently implies its highly spiritual style of beauty.

BERLIN UNIVERSITY.—This university has a professional staff of 165 men, the largest number being engaged with the philosophy faculty (literature and sciences together).

A SINGULAR CHILD.—Sioux City has a curiosity in the form of a child 3 years and 6 months old, with a head measuring 29¼ inches in circumference, mounted on a body no larger than that of an infant 4 months old.

MANUFACTURE OF SPIRITS FROM LICHEN.—Dr. Stahlschmidt (*Bayerisches Industrie und Gewerbe Blatt*) thus describes the process of making spirits from marine and terrestrial European lichens. The cellulose of the lichens or moss is converted into glucose by boiling with from 7 to 10 per cent. of the mass of hydrochloric acid (sp. gr. 1·165) by the aid of steam; the acid is saturated with chalk, and the saccharine matter brought to fermentation; 20 pounds of moss or lichen yield 5 litres of spirit at 50 per cent. anhydrous alcohol.

Original Lectures.

A LECTURE
ON
THE MENTAL STATE OF EPILEPTICS
AND
ITS MEDICO-LEGAL RELATIONS.

By MEREDITH CLYMER, M.D.

PART II.*

Now the natural outcome from this investigation into the mental state of epileptics, illustrated by the cases which I have cited, is, that the mind of the epileptic is rarely, if ever, entirely whole, and that the psychical derangements to which he is liable are exhibited under varied features. In many cases there is gradual failure of intelligence ending in total mental annihilation; others show anomalies of character and disposition which hardly go beyond harmless eccentricities of conduct, or at most involve a change of temper and habits; in some there may be an extreme perversion of affective life, and occasional explosions of automatic temper-fits, in which they lose the knowledge of themselves, but are generally content, with piteous action, to unpack their minds in words—

—tantum maledicit utrique, vocando
Hanc, Furiam; hunc, aliud, jussit quod splendida bilis;

or there may be those terrible outbursts of maniacal fury, accompanied with homicidal or suicidal impulses, or both. We must admit, too, that epilepsy may be manifested, at least for a while, by some mental disorder only, constituting the masked epilepsy of Morel, and which has been very stupidly called cerebral epilepsy, from some supposed analogy with spinal epilepsy, another odd misnomer. If a special name is needed, the term *psychical epilepsy* would be more proper.

The disposition which these psychical derangements have to express themselves in convulsive action, is not the least curious or interesting part of their clinical history. A distinguished pupil of the late Griesinger, Dr. Paul Jacoby, has attempted an explanation of the manner by which the morbid impulses of the insane are transformed into, and manifested by, musculo-motory efforts. We know, he says, that every perception (sensation, idea, image) may take on a motor character, and be directed towards groups of muscles, and that it has always a tendency to express, or interpret, itself by some movement or action. Griesinger himself first showed this fundamental fact of all psychical life, and represented the motory side of mental life as a gradual succession of events following the same principle, from the simplest reflex action, to the best known act of the will. This view has been assented to by the metaphysician Schopenhauer and the physiologist Schiff. Griesinger, moreover, calls attention to the fact that in insanity much depends upon derangements in the normal psychical reflex action, without the entire higher mental life being necessarily involved; and Guislain holds the same. Let me quote one or two sentences from Griesinger, in which he applies his theory to the subject under consideration. "It is worthy of note," he says, "that frequently in mental disease, this motory side of the soul-life and the musculo-motory function are both altered in the same morbid manner. Thus there happens absence of will, together with general paresis of movement, or a morbid exaggeration of the will, with increased muscular activity, as in maniacal fits; at other times the disease passes quickly from one circuit of action to another, as in an attack of epileptic convulsions, followed immediately by a psychical convulsive state, an attack of frenzy. But as the sensations and feelings are the more easily converted into instincts in proportion to their strength, so Will is developed out of the single perceptions the more readily according to the strength and persistence with which they enforce themselves. On this account the strongest ideas, at the end of their transition, pass forcibly into actions."

Let us now inquire whether there is any pathogenetic correlation between the convulsive phenomena in an ordinary epileptic fit and the psychopathic manifestations of epileptic mania. Many physiologists recognize an intimate connection between the emotions and the sensory ganglia, and particularly the medulla oblongata. Years ago Marshall Hall wrote: "Emotions, the passions, have their seat in the medulla oblongata, and act along the true spinal and ganglionic nerves." Later Schroeder van der Kolk expressed the same opinion; and Dr. Lockhart Clarke has, quite recently, said: "It is probable that the olivary bodies are the centres through which different movements are co-ordinated for expressing the passions and emotions." (*Philosophical Transactions*, 1868, p. 319.) Dr. Laycock observes: "Ideas, feelings, or desires may, during morbid states, pass downwards to the medulla oblongata, and there excite the activity of appropriate motor or kinetic substrata, without at the same time exciting any state of consciousness whatever. This is what occurs in all cases of automatic or unconscious cerebral action." (*Mind and Body*, ii., 443.) "The emotional faculties have probably their chief seat in this region [the medulla oblongata], and in the adjacent mesocephale," says Handfield Jones. (*Studies on Functional Nervous Diseases*, 1870, p. 5.) Now, if we may assume a special relation between the medulla oblongata and the emotions,* we can readily understand the relation between the convulsive and psychical forms of the disease. When speaking of the pathogeny of epilepsy, I told you that the medulla oblongata was the starting-point of the convulsive phenomena. It is the immediate centre which excites muscular contraction. Now, whatever is the cause of the irritation of this centre in the beginning of the fit, it is from it that is discharged through the sensori-motory apparatus upon certain muscles the impulsive force—now in the way of irregular muscular movements, and now as automatic muscular action determined by the nature of the emotion, in both cases the higher inteilectual centres being in abeyance, and probably in an anemic state.† In the latter instance it is the outlet of the abnormal direction of the emotional excitement. The physical and the mental symptoms proceed from the same cause. There is identity of pathogenetic origin, the difference being in expression, and the divers morbid disturbances are the result. We have seen that the maniacal outbreak may precede, follow, or take the place of, the ordinary convulsive fit, thus showing their relationship; and the hypothesis I have offered, based upon physiological grounds, seems to afford a probable explanation of their kinship.

Insanity in no form shows more conclusively the

* See THE MEDICAL RECORD, October 15, 1870.

* This hypothesis relieves the ganglionic cells of the cerebral hemispheres from the double duty of ideation and emotion.

† Dr. Carpenter relates, in speaking of Braidism or artificial somnambulism, that on an occasion he saw a blow which was struck alight by chance upon a second hypnotized subject within reach; the latter's combativeness being thereby excited, the two closed, and began to belabor one another with energy, and were with difficulty separated. Their passions were at the moment so strongly excited that even when separated they continued to utter furious denunciations against each other. (*Principles of Human Physiology*, 7th ed., p. 668.)

propriety of reckoning it amongst the diseases of the body than the mental disorders of the epileptic. And yet how little is the important principle of material disease being connected with derangement of the mind either recognized or understood. The somatic element has been thrust into the background by the psychical element, to the great prejudice of a successful study both of the nature and treatment of insanity. Pure metaphysics has utterly failed to teach us anything real and useful concerning the workings of the human mind in health and disease, notwithstanding that some of the mightiest and acutest intellects of the world have been engaged on the great problems of mental science.

The late Professor Griesinger, in his Introductory Lecture at the opening of the Clinic for Nervous and Mental Diseases in the Royal Charity Hospital at Berlin, on the 1st of May, 1866, boldly said: The diseases of the nervous system form one inseparable whole, of which the so-called mental diseases embrace but a moderate proportion. This position is by no means one which has been accepted as a matter of course. It is a scientific gain of the present day, the recognition of which will cause great changes, remove many errors, and must open up new developments in all directions. Dr. Maudsley holds the same language: "It is impossible," he writes, "that the true conceptions of mental disease can be acquired until men cease to regard its phenomena entirely from a psychological [*i. e.*, metaphysical] point of view, and consent to study them by aid of the established principles of physiology and pathology."

Such are the opinions of those teachers of mental science, in the spirit of modern thought, with whom it is my privilege to think alike. They show us the necessity of escape from what Dr. Whewell called "the thraldom of mere words," and of bringing the study of the mind, both in health and disease, within the limits of natural knowledge.

I know full well the prejudices which this method of investigating mental phenomena has to meet, and that those who teach it may be charged with materialism, the common cry of ignorance and intolerance, when they assault or run to cover. No accusation is more false. Mr. Huxley has most happily put it, that materialism involves a grave philosophical error, and every thoughtful man must repudiate it. Virchow has somewhere said: "There is a materialist dogmatism, as well as an ecclesiastical and an idealist dogmatism, and the materialist variety is certainly the more dangerous, because it denies its dogmatizing character and puts on the cloak of science; because it professes to be scientific where it is merely speculative, and because it strives to extend the limits of physical study to matters where this is evidently incompetent." In overstepping its proper and limited sphere of inquiry, and seeking the Unknowable in the "Whence? Why? and Whither?" it becomes the "science falsely so called" of the apostle, and will surely bring up in the materialistic slough. Whatever may be the quarrels between science and sacerdotal theology, true science has never assailed or discredited religion, and there is really no disharmony between them, for they have a common goal, Truth. In the peroration of the recent Gulstonian Lectures on the Unity of Mind and Body, by Dr. Maudsley, you may read these eloquent sentences: "To reckon the highest operations of mind to be functions of a mental organization, is to exalt, not to degrade, our conception of creative power and skill. . . I know not why the Power which created matter and its properties should be thought not to have endowed it with the functions of reason, feeling, and will, seeing that whether we discover it to be so endowed or not, the mystery is equally incomprehensible to us, equally simple and easy to the Power which created matter and its properties. No, science has not expelled the Divine from Nature. The grave of each superstition which it slays is the womb of a better birth."

If, then, the new philosophy, offspring of the bridal of physics and metaphysics—materialism and idealism—means the spirit of Truth, let us rejoice over the union, and honor the fruit. There can be no inevitable antagonism between science and religious thought, for science leads us to contemplate and love the

Fair humanities of old religion.

In spite of its detractors, scientific culture has its spiritual aspects. Nature, Sir Thomas Browne tells us, is the art of God, and the poet declares that

An undevout astronomer is mad.

Let us now briefly consider the medico-legal relations of our subject.

I know of no cases where you may be called upon as an expert, which will so often require nicer discrimination, fuller knowledge, and more patient investigation than to decide on the moral and criminal responsibility of an epileptic. Whilst in many instances the kind and degree of mental unsoundness are so undeniable as to be readily admitted, there are a number, where you will be beset with difficulties, and may have to encounter the sneers of the court and of counsel about "the theories of the doctors," "scientific hypothesis," and so forth, and hear a judge charge a jury directly in the face of facts.

In some cases it would seem that while the criminal may have had an irresistible impulse to commit crime, the law has an irresistible impulse to punish him. For though the law may be the perfection of reason and common sense, it would sometimes seem as if the exceptions exhibited were intended to prove the truth of the dictum. From the recklessness in the use of the plea of mental unsoundness in cases of homicide, it has come to be regarded with a good deal of suspicion both by the courts and the public. Great and good men, like the late Archbishop Whately for example, have advocated the hanging of all who pleaded insanity in cases of homicide. Besides, you may have at times to encounter one of those moral epidemics which suddenly burst out in a community, and demand a victim to stay its progress, and allow the mass of society to fall back into its accustomed state of indifference respecting crime. In these acute paroxysms of homicidal mania, public vengeance will not willingly be baulked. The case of Bisgrove, the epileptic homicide, of which I have already made mention, most strikingly illustrated this; and the savage vituperation of those who succeeded in saving the life of this miserable imbecile, by some of the leading London newspapers, which roared like young lions, was most discreditable.* It is an unpleasant position for the expert to be put in, but if he has his convictions he must stick to them, be self-forgetting and do his duty; and trust to living down the unpopularity he will be sure to earn.

Are all epileptics who have committed a criminal act to be considered, necessarily, as insane, and consequently irresponsible? Should the proof of being subject to epilepsy alone insure acquittal? I do not believe that the simple fact of an individual being subject to epilepsy will ever come to be admitted by legists as naturally divesting him of responsibility for his acts;

* A judicial murder has just been committed in England, under the influence of this acute homicidal frenzy of communities, in the case of Margaret Waters, the baby farmer; for however horrible her crime, it is quite clear that she was only legally guilty of manslaughter.

and the medical expert who maintains such a doctrine runs the risk of seriously compromising himself. In some cases, as I have said, the state of mental deterioration or perversion is such as not to admit of question; lasting traces of the disease leaving its mark on the mind. Again we meet with epileptics who are fulfilling all the duties of life, and whose real condition is not suspected; it is hard to assert that these persons are absolved from moral responsibility. We should be wrong then in always arriving at the conclusion that an epileptic is necessarily deprived of moral liberty, and therefore may claim immunity from the consequence of a culpable act. He may, in committing the offence, have obeyed some interested motive, and there may have been criminal premeditation, and at the time of the act full power of self-control, so that he could have refrained from the act had he liked so to do. You may have, then, no small difficulty in distinguishing the responsible criminal from the irresponsible lunatic. The mere fact of the commission of extravagant and vicious acts by an epileptic is not sufficient to divest him of responsibility and secure to him immunity for his acts. There must be proof and demonstration, beyond reasonable doubt, of his inability to control his vicious instincts. It must be shown, to quote Mr. Erskine's language, that "the act in question is the immediate, unqualified offspring of the disease." And you should always have in mind that you are bound to protect the rights of society as well as the rights of individuals. A general plea of insanity should not therefore absolutely protect every epileptic against the consequences of his act. A careful inquiry is to be made into the circumstances of each case, and the evidence thoroughly sifted. The period of the seizures should be learned; whether near to or remote from the time of committal of the act charged; the slowness or rapidity with which the seizures are recovered from; the mental state during the intervals—are all to be fully considered before you can decide whether the accused has been the victim of horrible imaginings, or yielded to a criminal suggestion of his free will.

There is a source of error, which I believe to be much more frequent than is supposed. I allude to those cases where the mental troubles follow nocturnal attacks. The examples are very many, and show how often proper inquiry is overlooked and what mistakes may follow, involving the liberty or even the life of the individual.

The following case is an apposite and instructive one, and points directly to possible oversight and error. I was lately consulted by a middle-aged gentleman, who told me that for a while he had been at times terribly affected in his mind, and in this wise: Without warning or any immediate provocation he would suddenly have the most horrible homicidal impulses towards certain persons who either really, or at the moment, he imagined, had injured, or slighted, or offended him. In his room, or in the street, or crossing a public square, the fit instantly seized him, and fancying the supposed evil-doer before him, he would strike at him with some fantastic murderous weapon—stabbing him in the neck, or breast, or belly, with a sharp instrument, or giving a blow on the head with a blunt one, the act being accompanied with the most violent reproachful language. He said he was not aware that in the street, or when any one was present, the gestures or speech were more than subjective; but if alone he knew that he spoke aloud, and suited the words to the action. The fit over, he always felt very much exhausted, with more or less loss of muscular power, particularly, recently, of the left extremities. Although occasionally in the company of some of the menaced persons, he had never at such times felt any disposition to harm them, or to behave towards them in any way that showed the feelings he at periods involuntarily experienced regarding them; but he was tormented by the apprehension that the time might come when he would be attacked whilst in their presence, and thus commit some horrid crime. He was a man of high moral tone and Christian training and practice, irritable, subject to temper-fits from childhood, but naturally of an amiable and generous disposition. He was greatly distressed at his infirmity, had for some time concealed it, and at last, dreading the possible consequences, sought advice. He said he had more than once decided to go voluntarily to an asylum, but was withheld from the fear of exposure and injury to his prospects and family. I found out in the course of my examination that he had had also at times suicidal thoughts, or, rather, that more than once the idea of the effects of the several methods of self-murder had been, as he said, irresistibly obtruded on his mind, and particularly the immediate sensation of a discharge of a pistol in his mouth; but, as he observed, he had never seriously meditated at any time suicide; it was rather, as he called it, an æsthetical contemplation of the means of self-destruction, without any especial desire to practically test them on himself. Although he had had many vexations from pecuniary losses and general bad luck, he was usually cheerful, not cast down by, nor given to brooding over, his troubles; and performed the daily duties of his calling, which did not demand any very great mental strain, easily and creditably. He had no headache, and his general health was excellent. After one of these spells his left arm would feel weary and his left leg weighted, along with some numbness and tingling in the parts; these sensations would soon pass off. He had had neuralgic attacks occasionally for many years, but they had become lighter and rarer. He never had suffered from epileptic fits, or, as he thought, anything like them; nor had any of his family. One day he asked me to prescribe something for a sore tongue, and on examination I found evidence of its having been bitten, which led me to believe that he was subject to nocturnal attacks; and on being questioned he admitted that often before falling asleep he had remarked that his jaw snapped, and sometimes his limbs jerked. I looked upon these phenomena, apparently so insignificant, as really the key to the psychical troubles, and the effects of treatment have tended to confirm the opinion.

An epileptic may have his attacks at long intervals and immediately after one of them have an irresistible disposition towards some criminal act, and then become apparently sane. Here we may have no indication to account for the morbid impulses if the antecedents are not known, or are overlooked; and an error in such cases is very possible if we form a judgment only by the present condition of the accused.

Delasiauve relates the following case in which epilepsy was not suspected for some time after the criminal act. A man had been confined in the Bicêtre as insane; soon after his discharge he killed his wife; he was acquitted on the ground of his previous temporary attack of mental alienation, and recommitted to the hospital. At this time there was no suspicion of epilepsy, and it was only subsequently discovered that this man, whose mind seemed perfectly sound, and continued apparently so up to the period of his death many years afterwards, had long suffered from nocturnal seizures. In this case there was a strong motive for the act, the murder having been committed under the influence of jealousy, and though he was of apparently sound mind at the moment of the deed, he escaped on

the plea of a previous attack of madness, without the true pathogenetic cause being thought of; and there can be no doubt but that this accidental acquittal was just, for had it not been for his confinement for his antecedent attack of insanity, he certainly would have been held morally responsible and suffered the penalty of the crime. The English law on this very point was laid down by Mr. Baron Bramwell in the trial of Dove, at Leeds, in 1856, in these barbarous terms: "If the prisoner was under a delusion that the deceased had inflicted some injury upon him, and murdered her whilst under that delusion, he would none the less be amenable to punishment."

A young man of good parentage and education was found guilty of the theft of some articles from a store, done at the instigation of his mistress. After he had been a short time in prison he had several epileptic fits, and he was transferred to Bicêtre, and it was then ascertained that he had been subject to them during five or six years.*

Dr. Duménil mentions the case of a young man who had been sent to prison for several robberies. Thirty-six hours after his committal he had a series of epileptic fits; he was removed to the asylum, from which he made his escape, and on the next day was arrested for an attempt at burglary. He relates another instance in point. A soldier, subject to sudden fits of passion, was tried by a court-martial for striking an officer. A medical inquest showed that he had had slight attacks of periodical mania. Dr. D., a long time afterwards, discovered that each of these attacks was preceded during the night by epileptic seizures, of which the man had no knowledge, and which had escaped the notice of those who had for several years slept near him. The same physician mentions that three of his patients had passed several years in asylums before the real nature of their infirmity was found out.

Many of these unfortunates are quite aware of and appreciate their terrible infirmity; they have a correct notion of right and wrong, but cannot control or resist their morbid impulses. They may have a foreknowledge of what will inevitably happen, and beg to be protected against themselves. Marc tells of an epileptic who, after being several times in an asylum, decided to remain there permanently, for his seizures were commonly preceded or followed by transitory fury, and he several times had attempted to kill his wife and servants. These mental impulses are not always irresistible, and may for a time be successfully opposed, but are liable at any moment to be transformed into acts against all the efforts of the will. After a criminal deed the epileptic may use this language: "I was urged on, something forced me, in spite of myself; I understood full well the atrocity of the act I was about to commit. I resisted for a while with all my might, but the time came when the horrid impulse mastered me. I had no power over myself, and had to yield to the horrible suggestion. No sooner was the act done, and I was myself again, than I saw it in its true light, I realized all the consequences, and was horror-stricken at what I had done; I lament my weakness, but I feel that my Will had nothing to do with it."

Now if the great legal test of responsibility—the full knowledge of right and wrong at the time of the act—be applied to such cases, most monstrous injustice would be done, and yet this has been the English law since it was laid down by Lord Hale, and is constantly quoted by leading authorities. As Professor Laycock remarks of this bloody-minded persecutor of old women: "He disregarded in his *dicta* alike the principles of pathology, and of common sense, and of ethics founded thereon." In the trial of Bellingham, for shooting the Right Honorable Spencer Perceval, 1812, Sir Vicary Gibbs for the prosecution maintained: "Although a man might be incapable of conducting his own affairs, he may still be answerable for his criminal acts, if he possessed a mind capable of distinguishing right from wrong. This upon the authority of the established law in all times, which law has never been questioned—upon the authority of the first sages of this country." Lord Mansfield, in his charge to the jury in the same case, said: "The simple question is: whether when he committed the offence he had sufficient understanding to distinguish good from evil, right from wrong, and knew that murder was a crime not only against the law of God, but against the law of the country."

Though in most instances there is no recollection afterwards of what occurred during the fit, there are others in which much method is shown in the madness, and all the circumstances that occurred perfectly recollected.

In the commune of Cravent, Loiret, France, lived the family Piednoir, consisting of a man and his wife, sexagenarians, and their son, aged twenty-seven, an epileptic. Except some extravagant ideas, the young man had shown no signs of mental derangement, and had always been affectionate towards his parents. On Easter Sunday he had had three epileptic seizures; that night he suddenly, and as quietly as possible, got out of bed, armed himself with some weapon at hand, and going to his mother, who slept in the same room with him, killed her with a single blow. He then went into the adjoining room where his father was asleep, and killed him too. He next attempted to force his way into the adjoining house, but its inmate made her escape, and by her cries aroused the neighbors, who coming to her aid tried to secure the murderer, but he eluded them, and proceeded to the house of a brother-in-law, a mile or two off, where he remained awhile, but made no mention of his deed. He returned home, barricaded himself in the house, and was only finally secured by a ruse. After he had become quiet, he confessed his crimes, the manner of their perpetration, &c.

It has been claimed that the epileptic may be responsible for some of his acts and not accountable for others. Here the debatable question of partial insanity is raised, which has been so stoutly objected to by those who hold to the unity and indivisibility of the mind. Lord Brougham said, using the language rather of a metaphysician than of a practical psychologist, we cannot with any correctness speak of *general* or *partial insanity;* but we may, most accurately, speak of the mind exciting itself in consciousness without cloud or imperfection,

* Since this lecture was in press I have read the following instructive case related by Dr. John P. Gray, in the *Proceedings of the Association of Medical Superintendents of American Institutions for the Insane; American Journal of Insanity*, for October, 1870. A man was tried for the murder of his wife. The plea of insanity was put in, but the counsel having given their entire attention to the fact of insanity, and little or none to the question of epilepsy, the evidence presented did not warrant the experts in considering the case one of insanity or of irresponsibility. During the progress of the trial the accused had a well-marked epileptic seizure in court. Dr. Gray sat beside him at the time, and addressed a note to the judge that the prisoner was in an epileptic state, and unconscious of what was going on. The court immediately adjourned. No witnesses were examined subsequently. The jury found a verdict of guilty, but the judge did not pronounce sentence. The prisoner was committed to an asylum by a later investigation before a county justice, on the ground that he had been an epileptic, was then an epileptic, and was therefore a person of doubtful responsibility. He remained in the asylum for several years, had epileptic fits, and became quite demented. Subsequently he had an attack of fever, and after recovery regained his former health and mental vigor, and at length was in a condition like that before his epileptic seizures. He was retained some years, but had no return of epilepsy. By the repeal of the law under which he was convicted he was discharged. Dr. Gray adds that he has since followed the case, that the man has conducted himself well, is earning a livelihood, and has neither insanity nor epilepsy.

but being morbid when it fancies; and so its owner may have a diseased imagination; or the imagination may be impaired, and the owner may be said to have lost his memory—language not very clear or satisfactory, but meaning nothing if not admitting unsoundness of mind on some subjects, and soundness on others.

The existence of partial insanity is now recognized by all alienists and practical psychologists, and on grounds which cannot be disputed. Even the mediæval Hale admitted that "there is a partial insanity and a total insanity" (*Pleas of the Crown*, 30); but he turned the dictum to the account of his bloody instructions, for he says: "And this partial insanity seems not to excuse them in the committing of any offence for its matter capital; for, doubtless, most persons who are felons of themselves and others are under a degree of partial insanity when they commit these offences." Though the theory is an elastic one, and, doubtless, one that in a criminal case may be improperly and dangerously applied, and frequently is, still it is a great truth of medico-mental science, though but lately proved and accepted generally. That a man may be insane, with an unimpaired intellect, or without the presence of delusions, may be assumed as unquestionable. With good intellection, his moral faculties may be undeveloped from congenital defect, and he may be utterly unable to distinguish good from evil.

You must bear in mind what I have already mentioned, that the morbid mental phenomena may replace the convulsive disorder. The epilepsy may be apparently cured, but the mind-troubles, which have not previously existed, or in a slight degree only, can now become rapidly developed in any of the several forms which I have described.*

Finally the question comes up as to the length of time before and after a seizure, that an epileptic should be considered as irresponsible before the law. Zacchias has laid it down that every epileptic should be held as irresponsible for any criminal act he may commit three days before and three days after a seizure. I think, from what has been said in this lecture, that no absolute rule can be laid down, and that each individual case must be considered on its own merits, and the different circumstances under which the several forms of mental troubles in the epileptic may be developed must be borne in mind.†

In respect to the testamentary capacity of epileptics, I will only detain you by remarking that the general principle which should guide you in any question which may arise is: that the same rules are to be applied as in any case where there is doubt of the mental state of the testator. The fact of his being an epileptic is not to influence the inquiry; though admitting the fact of more or less impairment of the mind of the epileptic, still, and it is generally so, their testamentary capacity cannot be questioned. Actual unsoundness of mind must be unequivocally made out; and, moreover, the connection between the ascertained mental condition and the alleged vagaries or wrongfulness of the testamentary disposition satisfactorily exhibited. Great caution is necessary on the part of the expert, and he should be careful to keep in the investigation his mind free from any bias which the fact of epilepsy may have upon it, otherwise he may become an instrument in the hands of unprincipled persons, to the injury of the innocent and the perversion of justice.

In conclusion it may be proper to say a few words concerning the marriage of epileptics. The only prohibitory enactment that I know of is an edict of a Bishop of Spires, which enforced heavy penalties against such as promoted them. In Denmark, the law permits the dissolution of a marriage if the complaining party was in ignorance of the fact at the time of contracting. Zacchias, Mahon, and the Faculty of Halle, all, in view of protective legislation, incline to restrictions more or less severe. The subject is often an embarrassing one to the physician, but one in which there is a right to his opinion, and from which he cannot escape. A general rule may be stated, that an epileptic cannot marry without danger to himself and the risk of unhappiness to those who should be dear to him. The effects of sexual intercourse are often disastrous to the epileptic.

With respect to the influence of heredity, and how far it is advisable to discourage the marriage of persons the parents of one or the other of whom have been epileptic, I will first say with Calmeil: that prudence requires the parties interested should always be apprised of the risks they run: next, where the epileptic offspring is in good health, and apparently free from all taint, and born a long time after the father or mother has become epileptic, and their attacks were of accidental origin, and other near relatives were free from the disorder, a favorable answer may be given, and probably no evil consequences will cause you to regret it.

* Dr. Geo. C. S. Choate, formerly Superintendent of the State Lunatic Hospital at Taunton, Mass., mentioned, at the Meeting of Superintendents, etc., at Hartford, June, 1870, the case of a young man who had been epileptic from early youth, but had not manifested many symptoms of impaired mind, and had been very docile. He took the bromide of potassium for a year, during which time he had no fits, but his mental condition much worsened, and though cured of his epilepsy he finally became intractable, and he was sent to the asylum, where he is now.

Dr. Gundry, of the Southern Ohio Lunatic Asylum, Dayton, Ohio, at the same meeting, said that a case had come under his notice in which, after six months of treatment by the bromide of potassium, the cry was raised, "you cured him of epilepsy, and the people wish he had epilepsy again, because he is so confoundedly cross they want him to have fits."—*American Journal of Insanity* for October, 1870.

† It has always been a question in legal medicine, within what period before or after a fit, an epileptic can claim immunity for a criminal offence. In cases of this kind, bearing in mind the cases that have been recorded, are we able to fix upon such a period? Is there any time when the epileptic can be considered as clearly free from the pathological effects of the disease? Can he ever commit a crime without being entitled to excuse? At any rate the criminal acts of epileptics should ever be regarded by the expert with great distrust, and receive the most exhaustive investigation. I think he is bound to accept the single alternative, either that the patient has entirely recovered beyond the reach of the epileptic disease, or that he is, in some degree of probability, still suffering from it. He is clearly entitled to the benefit of every doubt (Dr. Isaac Ray—*Proceedings of the Association of Medical Superintendents of American Institutions for the Insane. American Journal of Insanity* for October, 1870.

LARGE DOSES OF CALOMEL IN URÆMIC POISONING.

By O. H. SMITH, M.D.,

BROOKLYN, E. D., N. Y.

I beg to give you the results of large doses of calomel in the treatment of uræmic poisoning; and perhaps I can do it in no better way than by presenting a few cases in as brief a manner as possible.

When the urine is loaded with albumen, and every tissue in the body poisoned by uric acid, the brain overwhelmed with uræmic intoxication, and a general anasarca comes suddenly upon the patient, something must be done, and done quickly.

It is common to see pregnant women become dropsied about the 7th or 8th mo.; and sooner or later seized with convulsions, while the urine is loaded with albumen. In the same manner we see children, after a mild scarlet fever, become all at once dropsied, and an examination of the urine shows also a large amount of

albumen, and these are the cases that I propose to speak of.

How the calomel does its work, I do not attempt to explain. I am satisfied with the *fact*, and am willing to wait for the explanation until some future day.

Case No. 1. Mrs. M—, in her first pregnancy, became dropsical about the 8th month; the disease progressed until her confinement, when her body and limbs were much swollen. Urine loaded with albumen. During labor she was attacked with convulsions, the forceps were applied and delivery accomplished. The convulsions continued, and she was entirely unconscious for twenty-two hours. This case was under the care of an excellent physician, who desired me to aid him. Dr. Parker was called in consultation, and gave an unfavorable prognosis, saying nothing could be done but to try and lessen the severity of the spasms, and advised the inhalation of chloroform.

After some hours, with no relief, it was decided to give the patient a large dose of calomel, although she was expected to die before the medicine could have time to operate. The calomel (60 grains) was mixed with syrup and passed mechanically into the stomach, being washed down with a few table-spoonfuls of water. This was at 11 P. M., after several hours of unconsciousness. The chloroform was continued through the night at each convulsion, without any apparent relief. During the morning of the next day, the spasms were less frequent, and at 4 P. M. the bowels began to move with large fluid evacuations, while the convulsions became slight, and in the evening she began to show signs of consciousness, as if waking from a deep sleep. The patient went on to convalescence, and is now a beautiful and healthy woman, with several children. This case occurred twelve or fourteen years ago, and is familiar to many, as the patient was a most estimable lady, and had many friends. Dr. Parker saw her again after she became conscious and said the calomel had undoubtedly saved her life, but he could not tell how.

Case No. 2. Mrs. R——, of Greenpoint, ten years ago, nearly nine months pregnant, became dropsical and soon had convulsions. Saw her in consultation with Dr. Davis. Urine scanty and albuminous. She was ordered 20 grs. of calomel, to be repeated in three hours, and followed by cathartic.

Free operations followed, the convulsions ceased, dropsy disappeared, and she went on to a good labor in about two weeks. Similar cases can be given, treated in the same manner, and with like results.

In all these cases there was albumen in the urine, and consequently urea in the blood. No one will claim that calomel, or any other known remedy, will cure granular kidney, or Bright's disease; for here disease has produced a structural change in the kidney. But in these other cases, where we have all the symptoms of Bright's disease, and where death may occur from uræmic poisoning, we find calomel has a curative or controlling influence.

Case No. 3, is a man, Mr. L——, of N. Y. City, aged 50. He was supposed to have true granular kidney, and had been treated for that disease. He was under the care of Drs. White and Drummond, and when he was seized with spasms, several physicians were sent for.

Dr. White sent for me, but failed to meet me on account of other engagements. In order to get this case correctly I wrote to the Doctor, asking him to give me what he could recollect, and here is his reply:

"N. Y., Sept. 9, 1870.

"Dear Doctor—I remember the case, and will give you the particulars as far as I can recall them. I saw the man a few days since and learned what I could from him. He was a policeman, of temperate habits, and had been under treatment six or eight weeks. He had swollen feet, pain across the kidneys, urine scanty, and loaded with albumen. He had considerable general dropsy, and I considered him a bad case, although he was able to come to the office. Wet cups were ordered, and while undergoing the operation of cupping he was taken with convulsions. How many he had I do not know, but he was entirely unconscious, and had been for some hours when I first saw him after the attack. He had been seen by the Police Surgeon, Dr. Purdy, and Dr. J. Smith, of 49th St. They had ordered hot bottles and mustard. I think that was all, for it did not look as if much could be done. You had been gone a few minutes when I arrived and found your prescription: "℞. Hydrarg Sub-Mur. 3 i, one half to be given at once, and the balance in three hours." I gave the first half to him, and whether the other half was given or not I cannot say. But there were most thorough operations during the night, and in the morning I well remember finding him on the vessel, and wonderfully improved. I at that time was much impressed with the case, and I have the belief that the calomel not only relieved his symptoms, but actually saved his life. This was in 1865, and he had good health after for nearly four years, but is now suffering with symptoms of the same disease, and recently was confined to his bed for some weeks.

"I tried the same treatment on a patient with the same disease and in convulsions. Gave thirty grains, and with the same result, *speedy improvement.*

"Truly yours,

"E. White."

I will now give the result of calomel in the treatment of dropsy following scarlet fever. Mr. C. had three children sick at one time, and two, who had the disease in a mild form, suddenly became dropsical. The face, body and limbs were greatly swollen, and both pleural cavities in both children were so filled with water, that they could not lie down without danger of suffocation. The urine was full of albumen, and nearly solid when boiled, in both cases.

Diuretics and diaphoretics had no control over the increasing effusions. At last ten grains of calomel were given to each, and repeated in a few hours, and followed by a cathartic. In a short time the bowels moved freely, the dropsy began to disappear, and good recoveries followed. This was in 1860, and the boys are now fifteen and seventeen years of age, sound and healthy. From that time to the present many such cases have been treated in the same manner with satisfactory results. One more case and I am done. Master L., aged nine, in May last had scarlet fever so mild, that no physician was called until dropsy began to interfere with respiration. The left pleural cavity was nearly filled with water, and the heart embarrassed by effusions in the pericardium. Gave the little fellow twenty grains calomel, to be repeated in two hours, and carried my trocar at each visit, expecting to tap as a last resort. In a few hours the bowels began to move, respiration was slower, dropsy disappeared, and the patient had a good recovery. The urine was quite solid with albumen before calomel was given, and in four or five days hardly a trace could be seen by either of the usual tests. In this last case, no cathartic was given after the calomel, as the bowels moved sufficiently.

I would say that in almost all cases of dropsy after scarlet fever, I have given the Muriated Tincture of Iron, and it is especially indicated after the heroic treatment in the last cases recited.

There is no remedy that I know of, that is so certain to correct that dyscrasia, or diphtheritic state of the blood, which belongs to scarlet fever, as the combination of hydrochloric acid and iron.

I offer these cases, and the treatment, and these hints to the profession, with a simple statement of facts, and leave them to decide how the good work was done within the body. Calomel in large doses does act promptly and powerfully upon some of the secretions of the body, and becomes a great eliminator of the blood.

Recent scientific investigations have shown that mercury does not act upon the liver to increase the secretion of bile, but, on the contrary, less bile is secreted when the remedy is administered.

Will these scientific gentlemen turn their attention to the action of mercury upon the secretion by the kidneys?

When we find the kidneys secreting albumen, and leaving uric acid in the blood, and then we administer mercury, and find the kidneys take on their normal function, and eliminate the urea, leaving the albumen in the blood, we must infer, at least, that the remedy has produced some change in the action of the kidneys.

AMPUTATION AT THE HIP-JOINT.

By T. B. TOWNSEND, M. D.

NEW HAVEN, CONN.

The patient, Mr. B., from an adjoining town, presented himself for consultation in regard to disease of the left femur, involving a portion of the pelvis.

Some thirty years since he sustained a fracture of both bones of the left leg, which was tardy in its recovery, and which was followed from time to time by exfoliation of portions of the tibia, occupying a period of about five years. He recovered the use of the limb, and until some twenty years since had no return of the disease. At the end of that time it presented itself in the lower third of the femur of the same side, and gradually extended upwards towards the body, throwing off occasionally portions of bone of some considerable size, until it reached the pelvis.

At the time of consultation his condition was as follows, viz.: Limb shrunken, with the thigh flexed upon the body, and the leg upon the thigh. Complete anchylosis at the hip, four or five sinuses extending to and communicating with the upper portion of the femur and pelvis, which were discharging a sero-purulent fluid: system much weakened by previous abuses, but a buoyant and hopeful state of mind, with a determination to submit to the operation, and a conviction that it would be successful.

May 25, 1869, assisted by Dr. Jared Lindsley, of New York, and Drs. Harrison and Banks, of Wallingford, and others, I removed the limb by making the anterior flap, and then immediately ligating the vessels; the posterior flap was then made, and the large vessels secured. This procedure I was forced to adopt by reason of the anchylosis. The capsule of the joint was divided, and the bone torn from its socket, fracturing a small portion of the rim of the acetabulum; the neck and head of the femur being in such a state of disease that none of it could be left.

The arteries were found imbedded not in the ordinary connective tissue of the limb, but in a heavy fibroid deposit, which prevented the application of the ligature in the ordinary manner, rendering it necessary to pass a needle armed with a ligature beneath them at a distance from the cut externally, and tying as in the interrupted suture.

At the termination of the operation the pulse was hardly perceptible, and continued so until the following morning, at which time the patient rallied. He commenced slowly to improve, passing through a surgical fever of about two weeks, and gaining strength as the suppuration decreased and the repair continued.

The last ligature came away on the thirtieth day after the operation, but the stump did not heal soundly until after the expiration of four or five months.

At this time, sixteen months after the operation, he is in good health and without any return of the disease.

HYDROCELE IN A FEMALE.

By E. P. BENNETT, M.D.,

DANBURY, CONN.

Hydrocele in females is of such rare occurrence that most authors on surgery fail even to make mention of it, and many physicians claim that it never exists, and in an extensive practice of over forty years but one single case has come under my observation. This case occurred recently in a young married female residing in Putnam county, and was mistaken by a surgeon of some eminence for a case of inguinal hernia, who endeavored to reduce it, but failing to do so, pronounced it adherent and irreducible, and advised to let it alone. That such a mistake should have been made is not at all surprising, as it was a hydrocele of the round ligament coming down through the inguinal canal, and occupying exactly the place of inguinal hernia, and closely resembling one. She subsequently came under my care, and upon inquiry I learned that about five years since a small tumor had made its appearance, which had slowly and steadily increased in size until it had attained its present size, which was about as large as a turkey's egg. It had not been painful, was not attended with abdominal disturbance, had never receded when decumbent, and gave to the touch a feeling of fluid contents, instead of the doughy feel of hernia, and I therefore thought that, whatever it might be, it was not hernia; and upon a closer inspection I diagnosed hydrocele of the round ligament, although it was not diaphonous. So sure was I of a correct diagnosis, that I at once proposed an operation, to which she readily consented; and with the aid of a professional brother, who coincided with me in my diagnosis, I proceeded to cautiously lay open the sac, when we found to our great satisfaction that we had not blundered in our opinion. The serous contents of the sac having been evacuated, I injected it with a saturated tincture of iodine, and she speedily recovered, without the supervention of a single unpleasant symptom. This case is only important from its rarity, and the fact that most physicians are not aware that hydrocele can, or ever does, occur in the female; and my object in writing this article is not to record any remarkable achievement in surgery, but to call the attention of physicians to this subject, and thereby prevent mistakes which might be attended with disastrous results.

Syphilis a Cause of Abortion.—James T. Whittaker, M.D., Cincinnati, Ohio (*Am. Journ. Obstetrics*), after citing the different gynecological authorities upon this subject, says:

"From the very complexity of opinions it may be gathered that no constant anomalies of the placenta have been detected as yet in syphilis, though it still remains the opinion of all modern obstetricians that this is one of the most frequent causes of abortion, while the cases of congenital affection leave no room for any doubt of the possibility of intra-uterine transmission."

ON VIBRATION

CONSIDERED AS

A MECHANICAL INFLUENCE IN PROMOTING THE CAPILLARY CIRCULATION.

By A. F. A. KING, M.D.,

OF WASHINGTON, D. C.

The author of this article requests the reader to perform for himself the following experiment:—Take a small glass tube, such as is used for making pipettes, and heat it in the middle over a spirit-lamp. When the heated part becomes soft, pull the tube asunder as *rapidly* and *violently* as possible. Each half of the tube has now a fine capillary extremity. But it is *too* fine. Cut off a portion until the canal of the tube becomes easily visible, or until liquid that has been drawn into it by suction can be forced out by applying the mouth at the square end, *not in drops but in a continuous stream.* Now fill the tube, and, if it is properly constructed, on holding it vertically with the point down, not a drop of liquid will escape, for the capillary attraction of the tube overcomes the force of gravitation. The tube—still full, or partly so—is now to be placed horizontally, and held, *not very firmly,* by the square end, between the thumb and finger of the left hand. If the outside of the tube is now wetted, and the thumb and finger of the right hand (also thoroughly wet) are rubbed with some delicacy back and forth on opposite sides of the external surface, so as to cause vibration in the tube (just as we produce musical vibration in a tumbler by rubbing the finger over its moistened brim), the liquid in the tube will be projected in a visible stream from the pointed end *to the distance of two, three, and some particles of it even four feet.* The better to appreciate the distance, let carmine or ink be used instead of water, and have the tube directed over sheets of white paper spread out to receive the spray. If, while the tube is being rubbed, it is pressed against the edge of a table or some other hard body, so as *to interfere with its vibration,* the ejection of its contents is immediately stopped. The presence of air in the pointed end of the instrument, instead of liquid, also spoils the experiment. The narrow end of the tube being curved, crooked, or turned at right angles, makes but little difference to the result. It may also be observed that the stream projects with greater force when the wetted thumb and finger are being passed *towards* the point than *from* it, and for the reason that, in the former instance, the vibrations are made to concentrate or accumulate towards the pointed end. A number of other interesting facts might be mentioned, which the reader who wishes to pursue the subject may obtain for himself by using tubes of various size and shape, or pointed at both ends, or with liquids of different consistency and specific gravity, &c. Tubes thrown into vibration without any liquid project a feeble stream of air. Other results, some of them quite curious, may be obtained by working with colored liquids under water.

In submitting these experiments to Prof. Henry, of the Smithsonian Institution, to Prof. Schaeffer, of the U. S. Patent Office, and to some other scientific, as well as to many medical gentlemen, I have been gratified to learn that they are altogether original; nor am I aware that the effect of *vibration as a motor-power* has ever before been recognized.

But before the facts thus made known can be considered as elucidating the doctrine that vibration is an auxiliary motor-power in promoting the capillary circulation, it is necessary to prove:—First, that *elastic* tubes, like the blood-vessels, have the same effect upon their contents, when caused to vibrate, as *inelastic* glass ones; and, second, that the vascular tubes of the body really *do* vibrate. In proof of these propositions experiments are yet wanting;* and while it is improbable that the blood-vessels are made to vibrate, under any circumstances, with the same intensity as a glass tube when used in the manner above described, yet it is more than likely that, had we the same facilities for measuring infinitesimal degrees of force as we possess for rendering visible infinitesimally small objects, a certain amount of vibration might be discovered in the vascular capillaries under the various circumstances presently to be mentioned.

At any rate we already know, speaking in a general way, that a body moving slowly over a surface with which it is in contact, whether within a tube or on an open plane, will have the velocity of its motion increased when the surface along which it moves is jarred or vibrated. Familiar illustrations of this must occur to us all. A not inapt one is often furnished during microscopic examinations; we have only to tap or jar the instrument when a blood-corpuscle or other cell is passing slowly over the field, and it at once darts rapidly on, often beyond the scope of surface under examination.

Now, when a white blood-globule is (so to speak) lazily wending its way along the interior wall of a capillary vessel, or when a red corpuscle is elongating itself while passing a capillary too small to admit it in a globular form, or bending its elastic substance while rounding a capillary angle, or when (according to Conheim) a globule is in the act of insinuating itself through a pore in the capillary wall, why may not each and all of these processes be accelerated by the vibrations imparted to the vessels, and to the body in general, from the physical shocks that occur during ordinary exercise? In the simple act of walking, every step brings the os calcis to the ground with sufficient force to cause a vibration through the entire bony frame, and which must be felt, to a certain extent, in the remotest capillary and other tissues. The stroke of the blacksmith's hammer and the woodman's axe must produce a still more decided effect, and so of most other physical exercises, not excepting horseback, carriage, and railroad travel, &c.

But most of all must we note the vibration necessarily generated both in the column of blood and in the walls of the vessels, not only by the contractions of the heart, and the sudden closure of its valvular openings, but also by the shock of its apex-beat against the chest wall. In the lungs we may cite an additional important source of vibration, viz., that caused by singing and loud speaking, especially when, as is usually the case in the practice of such exercises, the walls of the air-cells, together with the capillary vessels ramifying upon them, have been first stretched to a high degree of tension by a full inspiration. Quite a powerful vibration must be imparted to the pulmonary tissues in the act of sneezing, and it is not impossible that a useful purpose is thus accomplished in hastening the circulation through vessels that are beginning to be congested from the individual having been exposed to cold. The act of laughing may have a somewhat similar effect upon the portal circulation.

Here, too, it may be remarked that the heart and

* To this end, however, I am now conducting some experiments, in the prosecution of which Prof. Henry (whose great experience in such matters affords hope that decided results may be obtained) has kindly tendered me his valuable co-operation.

lungs (organs the maintenance of whose capillary circulation is highly important), which are supplied with the additional sources of vibration just mentioned—the one by the impulse of its own apex, the other by vocal exertion—seem to have been thus provided for because they are as it were *pendant* organs, having no *solid* connection with the skeleton, and therefore likely to be affected in a minor degree only by the shocks imparted to the osseous framework during ordinary physical exertion.

In corroboration of these views we may cite the fact that during *sleep*, when there is a less demand for active circulation of the blood, all these sources of vibration cease except the apex-beat of the never-resting heart; and even with regard to *it*, we observe the shock less forcible in the recumbent posture than in the erect, because in the former the weight of the organ drags it somewhat downwards and away from the thoracic wall.

When the circulation is too active, as in the vascular excitement of inflammation, we enjoin rest (avoidance of vibration), and there is probably no kind of disturbance more intolerable to an inflamed part, or more unpleasant to the patient, than a succession of jars.

Furthermore, that the normal capillary circulation, and hence the general nutrition of the body, are promoted by exercises that insure vibration, appears from the otherwise almost unaccountable good result derived from riding in rough vehicles over uneven roads, and the like. Dr. Parrish, of Philadelphia, Dr. Wood tells us, attributed his apparent cure of pulmonary consumption almost entirely to riding daily over rough pavements in a vehicle *without springs* intentionally constructed for the purpose. Were this really the case, it would suggest the employment of vibrating chairs for invalids or others leading a sedentary life, and of benches similarly constructed for the use of hospitals and schools. The foregoing observations also afford an explanation of the utility of vocal exercises in early pulmonary tuberculosis, as also of the immunity from this disease said to be enjoyed by most great orators, the vocal vibrations maintaining the capillary circulation, and hence the normal nutrition of the lung.

Finally, I have presented these somewhat promiscuous observations thus hastily (but with the intention of rendering the subject more complete at a future time), in order to enlist the interest of physiologists and others, who, better than myself, may possess the facilities and ability to perform experiments in corroboration, or otherwise, of the proposition embodied in the title of this article.

Progress of Medical Science.

A New Method of Effectually Remedying the Defect of Hare-lip.—Dr. William Stokes, Jun., Surgeon to the Richmond Surgical Hospital (*Dublin Quarterly Journal*), presents, with plates, an ingenious operation for remedying the congenital malformation called hare-lip, which prevents the formation of a notch; also gets rid of the chance of that defect subsequently occurring. By his operation he gets rid of all the defects of other procedures, in which, in part or entirely, the principle of the utilization of parings has been adopted. For—

First. No subsequent curtailment of the projection at the lower extremity of the cleft is necessary.

Second. The procedure is applicable to all forms and varieties of hare-lip.

Third. There is no chance of portions of the soft tissues perishing from any twisting of them.

Fourth. There can be no subsequent puckering.

Fifth. There can be no subsequent notch, as previously mentioned.

Sixth. The possibility of any vertical sulcus or groove in the line of the cicatrix is also prevented, which is the case after Sédillot's, Malgaigne's, Samuel Smith's, and other operations.

(The reader is referred to the author's extended remarks upon the operation, accompanied with cuts, which are so interesting and connected that we should do injustice to Dr. Stokes by making extracts.)

As regards the time which is best for the performance of operations for remedying this defect, surgeons are much divided in opinion; some eminent operators maintaining that where it is possible all such operations should be performed before dentition, while others hold that better results are obtained in all cases where the procedure has been deferred until a later period. His experience leads him to adopt the views of the latter class, and his reasons are as follows:—*First.* That the structures at the period of life previous to dentition are so weak, soft, and pulpy, are ill able to bear the continuous pressure of the needles and sutures, and that consequently they are specially liable to the occurrence of ulceration and the subsequent formation of transverse cicatrices. *Second.* The hemorrhage which, even though it be extremely slight in amount, is, in very young subjects, fraught with some danger. *Third.* There is much difficulty in executing any of the plans that have been devised for the avoidance of the defects which sometimes subsequently occur. In support of his opinion he has the high authority of his colleague, Mr. Adams, and the late Dr. Samuel Maclean, who went so far as to assert that, if possible, in all cases operation should be deferred until after second dentition.

Nunneley's Artery Forceps.—In the operation for hare-lip, previous to any cutting with either scissors or knife, in order to get rid of the great annoyance of hemorrhage, which in young subjects is a matter of great moment, and in all cases, when it occurs seriously, interferes with the comfort of the operator, Dr. William Stokes, Jun., of Dublin (*Dublin Quar. Journ.*), invariably applies at each angle of the mouth one of the late Dr. Nunneley's artery forceps, and in all cases he has found that it effectually commanded the hemorrhage. Another advantage of these truly practical instruments is, that they enable the operator to dispense with the aid of assistants pressing with their fingers the lips in these situations, and of necessity impeding the operator to a greater or less extent.

Fractures of Clavicle External to the Coracoid Process Attended by Displacement. — Robert W. Smith, M.D., Prof. of Surgery in the University of Dublin (*Dublin Quart. Journal*), having on former occasions called the attention of the Pathological Society of Dublin to this subject, and demonstrated by numerous dissections that the opinion expressed by several eminent writers, that fracture of the clavicle external to the coracoid process was unattended by displacement, was not sustained by facts, and that the existence of an extra-coracoid fracture was generally indicated by a well-marked deformity, he now reiterates all his previous assertions.

Fractures of the Sternal Extremity of the Clavicle.—Dr. Robert W. Smith, of Dublin (*Dublin Quart. Journal*), publishes five cases of fracture of the sternal extremity of the clavicle (four left and one right), hap-

pening from less than three-quarters of an inch to nearly two inches from the sterno-clavicular articulation, with displacement or deformity.

In order to render the history of the displacement in fractures of the extremities of the clavicle more connected, he reprints upon the present occasion some of the conclusions at which he formerly arrived respecting fractures of the acromial extremity of the bone,—conclusions which subsequent experience has not induced him to alter:

1. In fractures of the acromial extremity of the clavicle, between the coraco-clavicular ligaments, when displacement occurs, it is in general limited to an alteration in the direction of the bone, by which the natural convexity of this portion of the clavicle is increased.

2. In cases of fracture between the trapezoid ligament and the sterno-clavicular articulation, the displacement of the outer fragment is considerable, and is frequently carried to such an extent that the fragments form a right angle with each other.

3. The doctrine of non-displacement in intra-rhomboid fractures has not yet been established upon so secure a basis as to justify its acceptance as a truth.

4. In intra-rhomboid fractures the displacement of the sternal fragment, if it ever occurs, is the exception; that of the acromial fragment, to a greater or less extent, constituting the rule.

5. The explanation is, that the former is firmly connected by strong ligaments to fixed and immovable parts, while the latter is under the influence of three causes of derangement of position, viz., muscular action, the weight of the upper extremity, and the mobility of the scapula.

6. The influence of these causes in producing displacement of the outer fragment is not confined to intra-rhomboid fractures.

7. In fractures of the inner extremity of the clavicle the nature of the derangement of the acromial fragment is uniform, and its direction constant, viz., forwards. The first rib offers a mechanical obstacle to its displacement backwards.

8. The rhomboid ligament, from its direction, would permit of the outer fragment being displaced forwards and downwards, to a limited extent, were the bone broken internal to it.

Paralysis of the Bladder, and Organic Infantile Paralysis.—Walter G. Smith, M.D., Assistant Physician to the Adelaide Hospital, Dublin (*Dublin Quart. Jour.*), refers to four cases of these affections benefited by repeated, and in some cases long-continued Faradization.

In regard to this mode of local application of *induced* currents, no demarcation is drawn between the so-called primary and secondary current. Dr. Smith has never been able to satisfy himself that there is any real difference, and believes that, if we simply keep in mind the greater intensity of the secondary current, and its consequent higher penetrating power, it is practically immaterial whether a stronger primary or a weaker secondary current is employed. He adds, that he is glad to find Dr. Russell Reynolds has arrived at the same opinion.

Hæmatoma Auris.—Dr. E. R. Hunn, of the New York State Lunatic Asylum (*Am. Journ. of Insanity*), has had frequent opportunities of seeing *hæmatoma auris* in insane persons, and remarks that a certain amount of deformity remains in those cases where absorption takes place without rupture, but it is not nearly so marked as when punctured. This affection is almost entirely confined to the male sex, and occurs in those forms of insanity which are incurable; in the great majority of cases the cyst undergoes rupture rather than absorption of the effused blood.

The two powerful idiopathic causes for the production of hæmatoma are: cerebral congestion, and centripetal irritation of the sympathetic system by the emotions.

The local treatment of this affection is a matter of but little if any importance. The constitutional treatment simply resolves itself into the general treatment of insanity itself. He lays down the subjoined conclusions: 1st. Hæmatoma auris consists in an effusion of blood into the space between the perichondrium and cartilage of the ear. 2d. It occurs as a rule in persons who are insane, and is only very exceptionally found in the sane. 3d. It accompanies those forms of insanity which are essentially chronic or incurable, and consequently its presence indicates a very unfavorable prognosis. 4th. It is idiopathic, depending upon a pathological condition of the brain, and is incapable of being produced by external violence alone.

Rheumatism with Chorea.—At a late meeting of the Berlin Physiological Society, Dr. Westphal alluded to the connection between rheumatism and chorea, and referred to cases of insanity, the result of rheumatism, which were complicated with chorea.—(*Am. Journ. of Insanity.*)

Senile Contraction of the Vagina.—Dr. Alfred H. McClintock, F.R.C.S., ex-Master of the Dublin Lying-in Hospital (*Dublin Quart. Jour.*), describes a senile contraction of the vagina which is not a *congenital*, but an acquired defect; neither is it a sequel of parturition, nor, as far as his observation goes, of any inflammatory or adhesive process.

In married women, and especially those who have borne children, the capaciousness of the vagina is very marked in front, behind, and around the cervix uteri, and the finger can be freely passed to the full depth of the vaginal cul-de-sac; and in virgins the finger can be carried around the cervix. This state of things is quite altered by the progressive diminution of the calibre of the vagina—which commences at its summit, and slowly advances downwards. When the contraction has reached the level of the os tincæ, the introduction of the finger into the vaginal cul-de-sac around the cervix becomes quite impossible, this part (cervix) being so closely embraced by the broad ribbon-like stricture. With the persistent increase of the constriction the os and cervix become quite encapsulated, and beyond the reach of touch or sight.

All the cases he has met with were women advanced in years—between fifty and sixty—only one was under fifty; and on this account he is disposed to regard it as some sort of atrophy connected with the decline of life, and the extinction of functional activity in the generative organs.

All his examples of this disease were women. Some had been sterile, but more than half had borne children. Only one patient was a widow; all the others were married, and living with their husbands. In every instance the menstrual function had ceased, even in one of the cases where the lady's age did not much exceed forty years. The chief interest of a practical character which attaches to it has reference to the question of differential diagnosis, from the liability of its being mistaken for serious organic disease of the vagina or uterus.

Dr. Matthews Duncan, of Edinburgh, states, in reply to an inquiry on the point, that he has seen many cases of *senile contraction of the vagina.*

Epithelial Cancer in a Girl of Fifteen Years.—Walter Coles, M.D., Parkersburg, W. Va. (*St. Louis*

Med. & Surg. Jour.), was called to examine a girl, æt. 15, with an obstinate sore on the great toe of the right foot, which proved to be an epithelial cancer, involving the nail. With the concurrence of several medical men he amputated the toe at the first joint. This case presents some interesting points: *First*, in the youth of the patient; and, *second*, in the fact that there is a very clear history of hereditary tendency to cancer in the family.

Paget remarks: "A few cases are on record, transmitted from book to book, in which what were epithelial cancers occurred before adult life. This fact seems to be borne out by statistics, and also that the tendency to the development of this form of malignant growth increases with the advance of age. In this case the patient's half great-uncle on the maternal side died of epithelial cancer of the cheek, at an advanced age; also an aunt on the maternal side, of malignant disease of the uterus."

MANAGEMENT OF CANCRUM ORIS.—There is no patient the practitioner is more solicitous or anxious about than the subject of *gangrene of the mouth*, and Dr. W. S. Edgar, of St. Louis, Mo. (*St. Louis Med. & Surg. Journ.*), invites attention to the prophylactic treatment as all-important. Among the ferruginous preparations the liq. ferri iodidi has his preference in these cases, both for children or adults; it should be given alternately with the citrate of iron and quinine, particularly in malarial regions. The local treatment is no less important; thorough cleansing of the ulcers and mouth twice a day with the nebulizer, using a weak solution of the chloride of sodium or chlorate of potassa; also the permanganate of potassa to correct the offensive odor of the mouth, and stimulate healthy granulation. If any escharotic is indicated, a strong solution of sulph. of copper—xxx gr. to the oz. of water—or paste of permang. of potassa.

EXPERIMENTS ON THE ABSORBENT POWER OF THE BLADDER.—Physicians and physiologists are by no means agreed on the power of absorption possessed by the mucous membrane of the urinary bladder. While some assert that the excrementitious substances of the urine would constantly be carried back to the circulation if this absorption took place, others deny this fact. M. Beclard asserts that the fluids contained in the excretory reservoirs (the urinary and biliary bladders) are in the process of absorption. We should remember that the epithelial lining membrane of these viscera consists of stratified layers of pavement epithelium, which is less easily traversed by fluids than the simple membrane of the serous cavities. Nevertheless, a slight absorption takes place in these organs. The morning urine, which has remained a part of the night in the bladder, is of a darker color than the urine of the day, and also than that which has been passed after taking fluids.

Recent experiments of Bert and Joylet confirm those of M. Ségalas, and demonstrate the fact that the bladder in health rapidly absorbs certain substances introduced into it. A solution of strychnia, one part in one hundred, was carefully injected into the bladders of several rabbits, causing their death at the end of four minutes, although a few milligrammes only of the salt had been introduced, and a part of this had been removed by injections of water on the first appearance of symptoms of poisoning. Autopsy showed that the mucous membrane of the viscus remained healthy. Injections of a solution of atropia did not kill the animal or sensibly diminish the pupil.

The possibility of causing certain substances to be absorbed by the healthy bladder offers a therapeutic resource of considerable importance; in cholera, for instance, where medicines cannot be absorbed by the stomach and intestines, advantage can be taken of the circumstance that the bladder is habitually empty, for the injection of certain solutions which experience has shown to be absorbed. During an epidemic of cholera, M. Brown-Séquard injected into the bladder of several patients laudanum and alkaline carbonates, and he was convinced that these substances were absorbed in considerable amounts. Experiments of a similar character have been tried in Germany and Italy.—*L'Union Méd.*

CANCER OF THE LIVER.—Dr. S. N. Davis, of Chicago, Ill. (*Chicago Med. Examiner*), in an interesting clinical lecture on this subject, gives the following treatment:—Pay particular attention to the diet. Milk and farinaceous articles are the best. Meat should be used only sparingly. For an internal remedy, he has realized the most benefit from some of the arsenical preparations with conium. The following is a good formula: ℞. Arsenite Ioda, gr. iv.; Ext. Conium, ʒ iss. Make a mass, and divide into sixty pills. Sig. Take one three or four times a day.

Anodynes sufficient to relieve pain should be given, selecting those that do not constipate, if possible. Among the best are fluid ext. hops, and lettuce. By such treatment the physician can do much to palliate the sufferings of the patient, and delay somewhat the fatal result.

A HIGHLY RECOMMENDED GARGLE IN SCARLET FEVER.—Dr. James S. Whitmire, of Metamora, Ill. (*Chicago Med. Examiner*), has used a gargle or throat-wash, in this and similar affections, that, in his opinion, is a great improvement over anything that he has seen recommended for this purpose. It is made as follows:—

℞.	Alcohol	℥ ss.
	Elix. of vitriol	ʒ ij.
	Sulph. alum	ʒ j.
	Creasote	gtt. xl.
	Ol. cinnam	gtt. xxx.
	Syrup. simp	℥ iijss. M.

The patient, if strong or old enough, may gargle with this mixture, or the fauces and pharynx may be swabbed by an assistant; and though this mixture will be found to be pretty sharp at first, yet the comfort that immediately follows its use makes the patient not only reconciled, but eager to have it used.

EXCISION OF THE HIP-JOINT.—In regard to this operation, Dr. Moses Gunn, of Chicago, Ill. (*Chicago Med. Examiner*), considers the following points to be well established:—1. The immediate risk of the operation is not great; death, when it occurs, being rarely expedited by the operation. 2. The prospects of cure are greatly influenced by age, the operation being much more successful in childhood than after maturity. 3. When the operation is resorted to, it should be freely executed, and all points of disease, either in the femur or acetabulum, completely removed. 4. A free drain upon the wound should be maintained until healing from the bottom occurs; for healing without suppuration is unattainable, even by the use of carbolic acid, and the presence of purulent accumulations greatly endangers a good result. 5. Only moderate extension during the healing process should be attempted, but that moderate extension is imperative.

SPONTANEOUS AMPUTATION IN UTERO.—Dr. George Pepper, of Philadelphia (*Am. Journ. of Obstetrics*), related at a meeting of the Philadelphia Obstetrical So-

ciety, a case of spontaneous amputation of the right arm in utero. The child was a well-developed female in other respects, weighed 9½ pounds, and seemed strong and well. The arm had been removed at about ¾ of an inch below the elbow; the stump was rounded and well covered, and presented two small depressed cicatrices. The bones could be distinctly traced, and were nicely rounded off. No trace of the hand and arm could be found, though very carefully and thoroughly searched for. The umbilical cord was of normal length and appearance, and there were no fibrous bands or shreds attached to the amnion.

Dr. J. F. Wilson had seen a case about nine months since, where the right arm was removed at the junction of the lower and upper two-thirds. No trace of the limb could be detected.

Dr. Robert P. Harris had seen several cases where the limb was not developed, and in all cases there had been rudimentary fingers or toes.

An Antidote to Chloral.—M. Liebreich of Berlin (*Lancet*) proposes to employ injections of nitrate of strychnia as an antidote in cases where accidents have occurred through an overdose of chloral or chloroform.

Hastening Labor in Cases of Puerperal Convulsions.—J. C. McMeehan, M.D., Cincinnati, Ohio (*Cin. Med. Repertory*), asserts that in the cases of puerperal convulsions he has witnessed, and in all the cases that have been reported, nothing has seemed to have had so good an effect as the delivery.

The line of treatment in puerperal convulsions is plain. Bleeding in certain cases, inhalation of chloroform, cathartics, ice to the head; but, above all, to watch the os uteri carefully, make frequent examinations, and as soon as there is a slight dilatation to rupture the membranes immediately with a trocar, or finger-nail, for the purpose of letting the liquor amnii flow away, and as quickly as possible deliver with instruments. In conclusion, he remarks that there should be no waiting for efforts of nature in these cases, for there is danger in delay.

Constipation of Infants.—Dr. N. S. Davis, of Chicago, Ill. (*Chicago Medical Examiner*), believes much of infantile constipation arises from the lack of the peristaltic action of the bowels, and to stimulate their fibres often uses with beneficial effect minute doses of tinct. nux vomica, perhaps 1 drop; syrup ipecac., perhaps 5 drops; and might add, sometimes, with benefit, syrup rhubarb or tincture belladonna.

Treatment of Malarial Toxæmia.—H. S. Hudson, M.D., of Selma, Alabama (*The Richmond and Louisville Med. Journal*), in an excellent paper on "Malarial Toxæmia," with report of an acute case, recommends the following treatment:—

1st. As cinchona and quinia are recognized as antidotal to malaria, the early and free use of these remedies would seem to be positively indicated.

2d. That the danger of disorganization of the kidneys should be early combated by measures calculated to relieve the congestion or inflammation of these organs. Free purgation and the prolonged and frequent use of the hot bath would, perhaps, best attain this object.

3d. That the frequent discharge of the gall-bladder should be induced, perhaps purgation, especially if produced by mercurial preparations, and the exhibition of liquid food would best accomplish this. Bidder and Schmidt state that this viscus is emptied about two hours after a meal.

4th. That the absence of fluids and urgent thirst point to the necessity of an abundant supply of whatever fluid can be administered, either by the mouth, rectum, or the peripheral absorbent system, calculated to supply this want. Of other remedial measures, stimulation, general and local, would seem to be the one most needed.

The history of the disease as it has prevailed since the year 1867 has been fully and lucidly detailed by Dr. R. F. Michel, in his monograph read before the Medical Association of the State of Alabama, and published under the name of "Hæmorrhagic Malarial Fever."

Remarkable Case of Hydatid Cysts of the Liver.—Dr. White, of Buffalo, N. Y. (*Buffalo Med. and Sur. Journal*), reported, at the June meeting of the Buffalo Medical Association, a case of hydatid cysts of the liver in a female, who was tapped several times between the years 1863 and 1870. The discomfort being insupportable, Dr. White, in the presence of a number of his medical friends, made an incision into the abdominal cavity, and found, a little to the right of the median line of the body, a large cyst filled with forty pounds of offensive fluid, which was drawn off. The sac, containing this fluid, was found to have its pedicle above and attached to the lower margin of the enlarged right lobe of the liver. The patient did not rally from the operation. On post-mortem examination the whole organ, with the exception of a small portion of the left lobe, had no appearance of liver, being rather an agglutination of degenerate growths, in which were interspersed cysts of various sizes. The weight of the liver, with the remaining smaller cysts, was 23¼ pounds. The weight of the fluid removed by the operation was 40 pounds. Now, allowing that four-fifths only of this fluid came from the larger cyst, in other words, that one-fifth of it was blood and ascitic fluid, fifty-five and one-quarter (55¼) pounds would be a low estimate for the weight of this liver with its cysts, which is about fourteen times its normal weight.

This case is reported because hydatid cysts of the liver are very infrequently met with by American practitioners, and because he can find no record anywhere of a liver acquiring anything like the dimensions here described. It is, he believes, unparalleled in size.

Uterine Hemorrhage.—Dr. Tyler Smith recommends a full dose of ergot of rye, immediately after the birth of the child, to prevent hemorrhage.

An Efficient Substitute for the Stomach-Pump.—John T. Hodgen, M.D., St. Louis, Mo. (*St. Louis Med. and Surg. Journal*), has contrived the following simple, cheap, and efficient substitute for the stomach-pump: Attach four feet of India-rubber tubing to a stomach tube, fill both with water by simply dipping it in the liquid end first, then compressing the elastic tube between the thumb and finger to keep the fluid from running out, introduce the stomach tube, lower the outer end of the elastic tube, and the contents of the stomach pour out as readily as if from an open vessel. When the fluid ceases to flow, dip the outer end of the tube beneath the surface of the water, elevate the vessel containing it, and the stomach is soon filled; lower again the outer end of the tube, and the stomach is emptied. This can be repeated as often as is necessary.

The advantages claimed for this simple contrivance are, that it may almost always be improvised, is of speedy and easy application, has no valves to become obstructed or deranged, and is less expensive than a stomach-pump.

The same principle may be applied in injecting fluids into the bowels, as it has been for injecting into the bladder, uterus, and vagina.

THE NEW MATRICULANTS.

THE various medical colleges have filled their lecture-rooms with students, and the fall and winter courses are in full operation. The introductories have been delivered after the good old fashion, and although in the main wearisome and trite to most individuals have doubtless proved interesting, suggestive, and encouraging to the matriculants. The advice offered, although stereotyped, has been sound, and, if accepted and appreciated by those for whom it has been intended, cannot fail to produce good results. But it is one thing to receive counsel, and another thing to be able to follow it. This truism applies with a particular force to the majority of young men who habitually engage in the study of medicine.

The obstacles in the way of their success as students first, and practitioners afterwards, are sufficiently numerous. Not the least of these is the manner in which they are compelled to prosecute their studies. They are told by their teachers that much time is required to master even the principles of the science, and yet their studies are crowded into an incredibly short period. They are compelled to listen to four or five lectures in the day, attend hospital clinics, dissect, and have private examinations, and be expected to find time to study besides. Each department is taught by an expert who, being anxious to crowd the greatest amount of material in the time allotted for his course; imparts the information in the most concentrated form, and at the end of the term the learner is expected to be better informed on all the different branches than is any single one of his teachers. The responsibility of thus crowding the students rests entirely upon the faculty, and is not favored by other members of the profession not interested in the size of medical classes or the amount of fees collected in a given space of time. Very many attempts have been made to correct this abuse, but, as is well known, to very little purpose; in fact such endeavors have made matters worse, by the formation of extra chairs without a proportionate extension of the lecture term. But it is sufficient to know that whatever might have been done has not been accomplished, and that the student is the sufferer for the want of one of the main elements to his success, one of the principal conditions the necessity of which is in theory so strongly recommended by his teachers. Under the present circumstances the student is compelled to make the most of his situation, and strive to do the best he can to accomplish the result at which he aims.

The character of the studies, and the manner in which they are pushed, proves the necessity of the possession of a mind which shall be quick to appreciate facts, and equally ready to appropriate them. This involves the indispensability of a very careful preliminary education,—a quality notoriously wanting among young men undertaking the study of medicine. We have always insisted that none but those who have enjoyed the advantages of previous culture should attempt to enter our ranks. This assertion has been made in the face of some brilliant exceptions to the rule. We all know of men who have left the plough and the shop, and entered directly upon the study of medicine with ultimate success, but the results of their endeavors only prove the possession of an extraordinary amount of application and capability, qualities which are rarely found combined. In fact, the exceptions are plainly made to substantiate the original proposition, as they tend conclusively to show how much better they would have succeeded had they enjoyed previous educational advantages. Again, we are warranted in saying, in this connection, that the occurrences of the past are not, as regards the rapid progress of our art, to be accepted as criteria for the future. The position of the student of our science at the present day is widely different from what it was years ago. The requirements of a general practitioner in olden times were merely nominal compared with what they are now. Then the stethoscope was a novelty, the microscope was rarely if ever used, the ophthalmoscope, laryngoscope, endoscope, thermometer, æsthesiometer, and sphygmograph were hardly dreamt of; now, however, all have become such absolute necessities in the different departments of our art that not to have some knowledge of their application is to plead unpardonable ignorance. Formerly the medical student restricted his studies to his anatomy and practical medicine; now he is expected to be conversant with text-books upon every department of our science. The student of a quarter of a century ago without a previous education might succeed, while the student of to-day is quite sure to fail. And yet, strange to say, notwithstanding so much more is now required of medical students in mental capacity to appreciate the multitude of important facts accumulated, they are not much if any better prepared to commence their work than were their brothers a half century ago.

The young man who now starts as a student of medicine without a preliminary education is a mistaken individual. If he imagines that in spite of his previous deficiencies he can make his mark, he has no

appreciation of the hard study before him. But, after all, he is not accountable for the delusion under which he may labor. The true responsibility rests with our medical teachers, who, no matter what they may say to the contrary, are practically ignoring the necessities of proper preparation by admitting to lectures every one who may choose to come. If the student had previously any misgivings as to his fitness to enrol himself as a matriculant, they are at once dispelled by the willingness, nay, eagerness with which he is accepted. There is not enough said, on the part of the faculty, regarding the necessities and the advantages of preliminary education, as there is too much danger of frightening the students from the school. The number of those possessing baccalaureate degrees is so small, that were only such accepted the class in attendance would be numbered by the score instead of by the hundred. And if it were, would the profession at large suffer? The profession, we think, would be willing to run the risk. What if the aggregate number of graduates should be lessened by such restrictions; would not the loss of the colleges be the profession's gain? Our ranks are crowded, but there is always room for good and well-trained soldiers. We can spare the ignoramuses, but we wish to welcome the properly educated. Every incompetent man who enters our lists is a reflection on the cause, and no right-minded practitioner, in view of such a fact, can help feeling a solicitude when he asks of the respective colleges now in session, How many of your number are properly prepared to enter upon their medical studies?

Reviews and Notices of Books.

A TREATISE ON PHYSIOLOGY AND HYGIENE for Educational Institutions and General Readers, fully illustrated. By JOSEPH C. HUTCHISON, M.D., President of the New York Pathological Society, Vice-President of the New York Academy of Medicine, Surgeon to the Brooklyn City Hospital, etc., etc. New York: Clark & Maynard. 1870. 12mo., pp. 270.

THIS work is designed mainly for a text-book in schools and academies, and consequently treats of the various subjects connected with physiology and hygiene in an elementary manner. It is written in a wonderfully concise style, and, for a work of its size, we are surprised at the amount of useful information it contains. The descriptions of the various apparatus and their functions are rendered practically interesting to the young student by the skilful interpolations of many very valuable collateral hints, comparisons, and facts. The illustrations are admirable and well chosen, and with a copious glossary leave nothing to be desired in the way of making every part of the work perfectly intelligible to the merest tyro. We unhesitatingly recommend it to the teachers of the young as one of the best works of the sort that has been published, and predict for it a well-deserved popularity.

PRACTICAL ANATOMY; a Manual of Dissections. By CHRISTOPHER HEATH, F.R.C.S., Assistant Surgeon to University College Hospital, etc., etc. First American from Second English Edition, edited with additions by WILLIAM W. KEEN, M.D., Lecturer on Pathological Anatomy in the Jefferson Medical College, etc. Philadelphia: Henry C. Lea. 1870. 12mo. pp. 572. (Sheep)

In adapting this popular Dissector to the wants of the American Student the Editor has made some very necessary modifications and additions. The order of dissection of the body in Great Britain is essentially different from that observed here, and it has been altered accordingly. This is certainly a very commendable feature of the work. The additions are numerous, both as regards matter for the text and illustration, and all are of a practical character. Among the former, we notice the incorporation of the researches of Duchenne as to the actions of the omo-hyoid and supinator longus muscles, the observations of Cielland on the ligamentous action of muscles, of Luschka on the nervous supply of the arytenoid muscles, and directions for preserving and injecting subjects. The illustrations are excellent and numerous.

THE PHYSICIAN'S VISITING LIST for 1871. Philadelphia: Lindsay & Blakiston.

THIS useful pocket companion preserves its well-known form, and is arranged respectively for twenty-five and fifty patients weekly. We believe it to be the most complete list published.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

STATED MEETING, OCT. 12, 1870.

DR. J. C. HUTCHISON, PRESIDENT, in the Chair.

MAMMARY CANCER—THE INDICATIONS FOR REMOVAL, ETC.—DOES AMPUTATION EVER DO MORE THAN TEMPORARILY ARREST THE DISEASE?

DR. FINNELL exhibited the left mammary gland removed by operation from an unmarried lady, aged forty-two. About two years ago she began to suffer from pain in the organ, coincident with which was the formation of a tumor. This latter gradually increased, as did also the distress. At the end of a year from the commencement of the disease its malignant character was recognized and amputation advised. The operation was not, however, permitted until Sept. 28. The nipple suffered the characteristic retraction. There was no enlargement of the axillary glands. In consequence of the extent of the disease it was thought best to remove the entire organ, which was done. The wound was closed with eight silver sutures, and the dressing referred to at the last meeting (carbolic acid, lime, and sweet oil) was applied. Dr. Rogers examined the specimen and pronounced it scirrhus.

In connection with this case he asked the opinion of the members present as to the justifiableness of removing malignant tumors of the breast. He was aware of a great difference of opinion upon the subject among different surgeons. His principal guide was the amount of pain which the patient experienced. He also asked the question concerning the utility of the operation as the arrester of the disease.

DR. HUTCHISON remarked that he invariably amputated breasts the subject of malignant disease when there was great pain, and when there were no evidences of the disease having extended beyond the mammary gland.

DR. EAGER stated that he amputated in March, 1866, the breast of a woman from Livingston county. The disease was scirrhus. That patient did well for four-

teen months, at the end of which time she died, in consequence of the transfer of the disease to the lungs.

Dr. Finnell recollected hearing the late Dr. Kearney Rodgers say that he had removed a bushel basket full of cancerous breasts, but that he would never perform the operation again.

Dr. Hutchison had seen a great deal of distress occasioned in cases of cancer of the breast by the application by ignorant persons of powerful caustics. He had seen one case in which the sloughing thus occasioned was sufficient to cause death. He is in the habit, when consulted for treatment of these tumors of the breast, to lay all the facts before the patients, stating to them that he has operated many times, and that, with a single exception, the disease had reappeared. If they understand all these facts and insist, as they generally do, upon the operation, he prefers to perform it rather than allow them to fall into the hands of quacks.

Dr. Mason asked what was the longest period that had elapsed between the operation and the reappearance of the disease. He had a case under observation which had been operated upon two years ago, and there was still no evidence of a return of the disease.

Dr. Eager referred to one patient of his from whom he had removed the mammary gland nine or ten years ago, who is still living. Subsequent to this operation he had performed two others, for the removal respectively of enlarged axillary and cervical glands. He also recalled a case upon which he had operated for removal of cancerous axillary glands, five years and four months after Dr. George Blackman had removed the breast for the same disease. The patient did well for six months, when she died, in consequence of the reappearance of the disease in the lungs.

Dr. Hinton remarked that the metastasis of the external disease to an internal organ was so much the rule that it had been used as an argument for the operation.

Dr. Finnell stated that he had removed both mammary glands, for supposed scirrhous disease, fifteen years ago. That patient is still living. From the circumstance of this long immunity, he was inclined to question the integrity of the diagnosis. Again, he had a patient, a neighbor of his, aged seventy-eight, who was in reasonably good health, and from whom the late Dr. R. K. Hoffman had removed, twenty years ago, a breast supposed to be cancerous.

Dr. Eager removed a breast in 1853, from a woman in Bayard street, and up to 1864, when she moved to Michigan, she was in good health. The disease was pronounced to be cancerous by the late Dr. Valentine Mott and several other surgeons, all of whom considered the case so desperate a one that they declined to operate. The patient then presented herself to the Dispensary; and avowing her determination to have some one remove it, and a consultation of the staff deciding in favor of it, the operation was performed accordingly.

Dr. Rogers referred to a woman, aged fifty-five, who presented herself at the Dispensary, from whom one breast had been removed fifteen years ago, and another ten years ago. She said that the surgeons called it cancer. Another woman had presented herself to his class minus a breast, the organ, according to her statement, having been removed for cancerous disease twenty-five years ago by the late Kearney Rodgers.

A TOE TORN OUT BY THE ROOT, WITH EXTENSOR AND FLEXOR TENDONS ATTACHED.

Dr. Finnell exhibited a second specimen, consisting of the right great toe, attached to which were six inches of the long extensor and twelve inches of the long flexor, with a portion of the corresponding muscle. The whole was torn from the foot of a girl ten years of age, by the toe being caught under the edge of a truck, and being drawn along while the latter was being unloaded of coal.

Dr. Mason remarked that he had seen, at Bellevue, the thumb of a boy that had been torn off, to which was attached a considerable length of the extensor pollicis.

TAPE-WORM EXPELLED BY TURPENTINE.—THE EFFECTS OF LARGE AND SMALL DOSES OF THE REMEDY—TWO OUNCES MAY BE GIVEN WITH IMPUNITY!!

Dr. Freeman, of Brooklyn, presented a tape-worm sixteen feet in length (about four feet of which was in fragments), which had been passed by an English girl, aged thirteen years. She had been treated for tape-worm five or six months ago in England, but without any gratifying result. On the 3d of October, having fasted for twenty-four hours, two ounces of fluid extract of male fern were administered, followed the next morning, she still fasting, by an ounce of castor-oil and a drachm of oil of turpentine. This latter dose was repeated during the day. No portions of the worm were passed. She was let alone until the following Friday, when *two ounces* of oil of turpentine, in half a teacupful of milk, were given, and in the course of three or four hours afterwards twelve feet of the parasite came away, together with forty or fifty small pieces. The case was interesting, as proving the efficacy of the old-fashioned remedy, oil of turpentine. She suffered no bad symptoms from the large dose of turpentine, but the small ones produced more or less strangury.

Dr. Finnell remarked that had the patient died, there would have been no difficulty with a coroner's jury in arriving at a verdict of death from an overdose of turpentine. The remedy, nevertheless, seemed from the results of the case to be well chosen.

Dr. Whitall recalled a case in which he had administered on one occasion an ounce of pumpkin-seed in half a pint of water, and in which thirty-eight feet of the worm had been discharged alive. Finding it necessary, three months after, to treat the patient again for the same trouble, he administered two drachms of the essential oil of felix mas, followed the next day by two ounces of castor-oil. This resulted in the passage of four feet of the tenia, dead.

Dr. Hutchison had some time ago asked Dr. Squibb what was the best remedy for tape-worm, and the reply was, two ounces of oil of turpentine. The remedy in large doses acted as a purgative, but in small quantities, as in Dr. Freeman's case, was apt to produce strangury.

Dr. Hart asked if any of the members had tried the new remedy, Kousso. He had employed it on several occasions with good results.

Dr. Post stated that Dr. Mott used to relate cures of tetanus by drachm doses of oil of turpentine, but such never escaped strangury. Dr. P. thought that the danger of large doses was inflammation of the intestines.

Dr. Freeman remarked that in his case the purgation was not very active, the patient having only three or four evacuations during the day. In answer to a question, Dr. Freeman repeated that he used milk as a vehicle.

Dr. Hutchison replied that Dr. Squibb, having himself suffered from tape-worm, took the turpentine undiluted.

Dr. Finnell referred to a case in which extreme hypercatharsis was induced by the administration of a

drachm of oil of turpentine in an ounce of castor-oil.

Dr. Peters remarked that kousso was used in Abyssinia, where tape-worm was very common, with as much freedom and frequency as was catnip with us. The effects were not, however, very satisfactory, as the cause which produced the tape-worm in that locality—the eating of raw meat—was constantly operating. On the whole he did not think it was any more useful as a remedy than was the pumpkin-seed, male-fern, or turpentine.

URINARY CALCULI—PROFUSE HEMORRHAGE FROM NECK OF BLADDER.

Dr. Mason exhibited some large urinary calculi removed by operation from a man sixty-six years of age, who had suffered from symptoms of stone for the past ten years. The patient was a manufacturing jeweller, and, with a few exceptions, when he had attacks of severe cystitis, attended with copious hemorrhages, he was able to attend to his vocation until two weeks before his death. His urine was milky and ammoniacal, and contained large quantities of mucus and pus. At the time Dr. M. saw him he was compelled to pass his water every three or four minutes, which necessitated the wearing of a urinal. As the result of an examination the patient was told that he had a large stone in his bladder, with one and perhaps two smaller ones, and that besides there was enlargement of the prostate. This opinion coincided with those of other gentlemen who had previously examined the case. The operation of lithotomy was advised, but having lately heard a great deal of the good effects of crushing, he desired the latter operation. Dr. Mason told him that it was feasible to attempt to crush the smaller stone, but not so with the larger one. Lithotripsy was performed upon the smaller stone by Thompson's instrument, and the operation was successful. The next morning the patient felt so well that he went out, and as the result of the indiscretion was attacked with a violent cystitis. This was on the 2d of August. He was then suffering intensely from a constant desire to pass his water. Lithotomy was then advised, as much for the purpose of relieving the tenesmus as the removal of the stone. Dr. Parker, who was called in consultation, unqualifiedly sanctioned the measure. During the afternoon of the 3d of August, Dr. Mason performed the lateral operation for stone. As soon as the bladder was emptied a gush of venous hemorrhage took place. So rapidly did the blood flow that fears were entertained of his immediate death. The wound was opened, but no distinct source for the hemorrhage was discovered. It seemingly came from the neck of the bladder. Ice was applied, but failed in arresting the bleeding; a catheter was then introduced, and the wound plugged with dry lint. It was necessary afterwards to soak the lint in persulphate of iron, but even then the blood did not cease to ooze until the patient was straightened out in the recumbent position, and then the arrest was instantaneous. He rallied surprisingly well from the operation, and went through a short and sharp attack of diarrhœa, but on the fourth day he was seized with the symptoms of uræmic poisoning, from which he soon sank and died. Dr. Mason being at the time out of town, Dr. Carmalt made an autopsy about three hours after death, and found three large roughened phosphatic calculi in the bladder. That organ had its coats much thickened, and its anterior surface was firmly adherent above the pubes. The prostate was not enlarged, but the peculiar position of one of the calculi, in consequence of the bladder being drawn upwards, gave rise to the mistake in that part of the diagnosis. The left kidney, which was the only one that could be examined, was very much enlarged, was fatty, and had undergone cystic degeneration. Both ureters were very much enlarged. The three calculi weighed collectively just twelve ounces.

Dr. Mason, in conclusion, remarked that the patient had, during the last few months of his life, taken regularly Lee's alkaline pill.

Dr. Dalton thought that the latter circumstance explained the presence of the roughened prominence, or extra deposits on the surface, of the stones.

HOW SOON AFTER DEATH SHOULD AN AUTOPSY BE MADE?

Dr. Finnell stated that it was a rule with him never to make a post-mortem examination sooner than six hours after death. He recollected having performed an autopsy a little too soon. Such a procedure, to say the least, was unpleasant. He had frequently noticed that in criminals, even three or four hours after death, it was very easy to produce violent contractions of the muscles by pricking the skin with the knife.

Dr. Dalton remarked that if Dr. Finnell's objection to early autopsies was based upon a fear that death might not have taken place, it was best to fix no absolute rule as to time, but wait until cadaveric rigidity should occur.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, October 20, 1870.

Dr. H. D. Bulkley, President, in the Chair.

The President stated that Dr. T. C. Finnell would be the biographer of the late Prof. Gunning S. Bedford.

PULMONARY TUBERCULOSIS.

Dr. Austin Flint, Sen., then read an instructive paper on "Recent Views in Relation to Pulmonary Tuberculosis," of which the following is an abstract:—

The questions to be thus considered may be divided into those relating, *first*, to the tuberculous products, and to tuberculization; *second*, to the causation of pulmonary tuberculosis; and *third*, to the treatment.

The speaker stated clearly the prominent late views relating to the morbid products which for more than half a century have been called tuberculous, and to tuberculization—these views were from a histological stand-point—and spoke as follows:—

To discuss their merits might seem presumptuous in one who is not a practical histologist. But the great majority of those who are expected either to adopt or reject views founded on histological data are not, and cannot be, workers with the microscope. They cannot be expected to confirm or correct these data by their own observations. They must be content to compare the testimony of different observers, and judge for themselves according to their confidence in the observers. They may be competent, however, to exercise their judgment as to whether the data are sufficient to warrant the views which are thereon based. They may even be better qualified to do this than those who draw deductions from original observations; for experience has shown abundantly that microscopical observations are peculiarly exposed to error from the bias of speculation or preconceived convictions.

With respect to purely histological points there seems to be, for the most part, agreement among practical histologists. Different microscopical observers do not differ as to the appearances under the microscope. But there is not, as has been seen, the same agreement concerning the conclusions: there is much discrepancy in the interpretation of the appearances. Virchow and the disciples of the "cellular pathology" interpret cer-

tain anatomical elements to mean proliferation of normal cells. Robin, Bennett, and others, explain their production by a spontaneous generation. The cheesy metamorphosis, tyrosis, or granulo-fatty degeneration, of which so much has been said of late years, is perhaps inferred rather than proved; it is a mooted point as to the inflammatory or non-inflammatory character of the tuberculous granulations now recognized by many as the only true tubercles. Admitting that the so-called tuberculous infiltration is an inflammatory product, it is not certain that the primary process is an inflammation; at all events, there is room here for doubt and discussion; the relationship between the true products just named is a topic for directly opposite opinions. It is plain that the revelations of the microscope, valuable as they are, have not, as yet, been sufficient to settle these and other pathological questions. Much stress is laid by recent observers on the essential difference between these two products; yet one of the most distinguished of those engaged in the study of tubercle, namely, Villemin, declares that he "thinks" (to quote his own words) "there is ground for returning to the ideas of the great Laennec and the judicious Andral in behalf of the unity of tuberculosis."

It is deemed a highly important object, as a result of late histological researches, to call the affection heretofore known as infiltrated tubercle, a pneumonia. Let it be granted that there is a strict pathological propriety in this, the practical advantage which is gained is not very apparent. The long-established points in morbid anatomy which distinguish this affection from other forms of pneumonia remain unchanged. Here is a product which is absorbed with great difficulty, if at all, whereas the intra-vesicular product in ordinary pneumonia is generally, and often rapidly, removed by absorption. The former leads to abscesses, and to cavities which very rarely cicatrize; the latter seldom ends in abscesses, and when they occur the cavities resulting from them tend to cicatrization. The tuberculous pneumonia is a bilateral affection, the instances in which it is confined to one lung being rare exceptions to the rule; the reverse is true of ordinary pneumonia. On the other hand, contrast the tuberculous pneumonia with the chronic form in which the morbid product is interstitial, and these points of difference are not less striking. If it be resolved to call the affection a pneumonia, some qualifying term, denoting its distinctness of character, is certainly important. The word *cheesy*, or the more refined synonym *caseous*, is objectionable on the ground that for it to have any precision the age and the kind of cheese to which it is analogous should be stated. The name "chronic catarrhal pneumonia" must derive its significance chiefly from the supposition that the pneumonia supervenes upon a bronchitis, which is a supposition, to say the least of it. Tuberculous pneumonia seems the most appropriate term. This term is objected to on the ground that the affection is not always, although often, associated with true tubercles, that is, the gray granulations. To call a pneumonia without tubercles tuberculous, would, of course, be a misnomer. The objection is a valid one only in view of the hypothesis that tubercles or granulations are consecutive to, and dependent upon, the pneumonia; the latter, accordingly, existing for a time without, and in some cases not being followed by the former. Niemeyer carries this hypothesis so far as to say that "the greatest danger for the majority of consumptives is, *they are apt to become tuberculous*"—a curious statement when it is considered that, assuming the correctness of the hypothesis, to determine whether the pneumonia be or be not associated with tubercles, is confessedly rarely within the grasp of diagnosis. As a concluding remark, in connection with this division of the subject, the distinctions and names which have lately been introduced can hardly be said to simplify our knowledge of tuberculous disease. I will content myself, in illustration of this remark, with citing the nosological divisions in the late treatise on Pulmonary Phthisis by Hérard and Cornil—a work of labor and ability, and containing much valuable information.

These authors treat of the following forms of disease as entering into the study of pulmonary phthisis:

1st. Lobar tuberculous pneumonia; 2d. Lobular tuberculous pneumonia; 3d. Generalized granular phthisis; 4th. Generalized granular phthisis, with pneumonia; 5th. Partial granular phthisis; 6th. Acute or galloping phthisis; 7th. Generalized caseous lobar pneumonia. Into these seven varieties are resolved the chronic and acute phthisis of other authors.

The Causation of Pulmonary Tuberculosis.—The discovery by Villemin of the inoculability of tubercle stands out in strong relief among the conflicting and perplexing views which have been noticed. The inoculability of tubercle is a positive indubitable fact, which not unlikely will constitute a highly important epoch in the history of tuberculous disease. Connected with this discovery are certain questions not as yet settled. The specific character of tuberculosis is one of these. In other words, does the matter inoculated, when the disease is thus communicated, contain a special virus? Villemin claims that his experiments prove the affirmative to this question, and establish for tuberculous disease a specific character such as belongs to variola, scarlatina, syphilis, and glanders. His work on tuberculous phthisis is a masterly effort to show this by collateral evidence, as well as by the experiments establishing the inoculability of the disease. On the other hand, Lebert, Wryss, Waldenburg, in Germany, Colin, in France, and Andrew Clarke, Simon, Sanderson, and Wilson Fox, in England, have made experiments which appear to show that inoculation with other than tuberculous products (using this term in its widest sense) is sometimes followed by the development of tubercles in the lungs and different organs. Villemin claims that in these experiments either the products furnishing the matter for inoculation contained the tuberculous virus, or the products following the inoculation were not true tubercles. The settlement of this point by continued researches is evidently of much importance in its bearing on the question as to the specific character of the disease.

From the fact of inoculability springs another question, which need only be stated for its practical importance to be sufficiently obvious. Inoculation proves contagiousness in the strict and proper adaptation of the latter term; but is not the disease communicable by infection? This is the question now referred to. May not material emanations from tuberculous patients be received into the air-passages, and the disease in this way produced? Contagion does not prove infection—a fact of which syphilis is an exemplification—but taking into view morbid emanations which must be contained in the expired breath of patients affected with tuberculous disease, the possibility, if not probability, of its being sometimes thus communicated becomes an important point for renewed clinical study. And, pending the accumulation and investigation of facts, it is certainly a wise precaution to enjoin upon healthy persons, and those already tuberculous, to avoid, as far as practicable, an atmosphere which, from defective ventilation or the congregation of phthisical patients, or both, must abound in the suspected emanations.

From the time of Laennec a tuberculous diathesis has been supposed to be largely involved in the causation

of pulmonary tuberculosis; but, according to the views of some distinguished writers of the present day, this diathetic agency has been greatly overestimated. Villemin repudiates altogether the existence of a diathesis which is independent of the introduction within the system of a special virus. Others, for example Niemeyer, while they do not ignore a constitutional predisposition, think that its causative influence is vastly less than has been supposed, and that a proportionately greater agency is exerted by local exciting causes. The advocates of this view consider that an active, special diathesis does not exist, but only a certain amount of vulnerability (to use a word of recent application) arising from an enfeebled power of resistance to the local causes of disease. This view, in fact, almost does away with a diathetic influence, since the term diathesis denotes a predisposition to a particular form of disease. It has been hitherto believed that tuberculous disease is developed chiefly, and sometimes even exclusively, as a result of a special, determining, constitutional, morbid condition. This is the idea attached to the term tuberculous diathesis. Local exciting causes have been regarded as of secondary importance, being never, in themselves, sufficient to produce the disease, and in many cases not being included in the causation. Here are questions of great practical importance. The teachings of Niemeyer are in strong contrast with the views which have been, and are still, generally held by physicians; and it is needless to call attention to their direct and important bearing on treatment.

These views are to be sustained, or otherwise, not by arguments, but by evidence derived from clinical experience. Is it true that tuberculous infiltration, or pneumonia, as determined by physical signs, is preceded generally or frequently by bronchitis? The answer to this question in the negative purports to be based on clinical facts. So far as one can judge from publications, the affirmative, if not merely a speculative or rational conclusion, is supported, as yet, only by the impressions formed on a limited experience.

The latter answer is a revival of an old belief which has never been eliminated from the popular mind. If the question is to be settled anew, this can only be done fairly by a fresh appeal to clinical observation. It is practicable to settle the question in that way. The existence or non-existence of bronchitis, or a bronchial catarrh, antecedently to the presence of signs denoting tuberculous solidification of lung, is a point which, if the opportunity be offered, a competent clinical observer can determine in individual cases. Until the question is settled in the only way in which it can be settled, let us not accept the new view because it is affirmed, or because it is thought to harmonize with other views.

The remarks just made are alike applicable to the question whether hæmoptysis stands in a causative relation to tuberculous disease. The affirmation of such a relation, no matter by whom made, and the reasonableness of it, or its consistency with other views, are of no moment except in so far as they are sustained by clinical evidence. The question is to be settled by determining whether hæmoptysis, occurring when tuberculous disease does not exist, is followed by this disease in a proportion of cases sufficiently large to show a relation of causation. Clinical observation is competent to determine this point, and, until this is done, it is the part of prudence and philosophy to hold the mind in abeyance with regard to the adoption of this, as of the other of the views just stated.

The Treatment of Pulmonary Tuberculosis.—Within the recollection of the older physicians of the present day, the treatment of pulmonary tuberculosis has undergone an entire change. The measures in vogue thirty or forty years ago, were those which have been known as antiphlogistic, namely, venesection and local blood-letting, mercurialization, and active counter-irritation. With these were conjoined a restricted diet and confinement within doors.

Impartial observers who are able to compare the success of treatment then and now, must bear testimony to a great improvement. The proportion of recoveries is certainly much greater. When recovery does not take place, the disease is much oftener non-progressive, and, when not stationary, its progress is more slow. Death is not so often preceded by a long period of confinement to the bed and suffering from extreme debility and bed sores.

In these respects the contrast is very striking, and it is fair to attribute it to the change in treatment. Of late years the so-called antiphlogistic measures have fallen into disuse; and, in place of these, tonic remedies and alcoholic stimulants have been much employed, together with cod-liver oil, a generous diet, and life out of doors.

It is not easy to determine how far the improvement in the success of treatment is due to the abandonment of measures formerly employed, and how far to those which have been substituted, but that the former were injurious can hardly be doubted. Of the measures now in vogue, there may be differences of opinion with reference to the relative importance of those which are, in the strict sense of the term, therapeutical, and those which come under the head of diet and regimen; but I think few are to be found who do not regard the latter as vastly more important than the former. It is by no means uncommon for cases to be treated exclusively by hygienic measures.

Now, it is proposed to return to some of the measures which had become almost obsolete in practice.

In the recent treatises by Hérard and Cornil, and by Niemeyer, blood-letting is advocated as a measure important in certain cases of the common form of pulmonary tuberculosis, namely, that known as infiltrated tubercle. In the first-named of these two treatises, even venesection is recommended, and in the second local bleeding by cups or leeches. Hérard and Cornil advocate the use of the tartrate of antimony. They advise confinement within doors during the winter season. Niemeyer goes further, and advises confinement to the bed whenever febrile phenomena are present. These measures of treatment are based on the pathological view which considers infiltrated tubercle as a form of pneumonia; they are employed, in other words, as antiphlogistic measures. Hérard and Cornil state that the therapeutical indications are nearly the same as in cases of frank pneumonia; and Niemeyer states as a reason for giving to the affection the name "chronic catarrhal pneumonia," that thereby "its prophylaxis and therapeusis are promoted."

This new view of the treatment of pulmonary tuberculosis seems to me to illustrate the tendency to engraft therapeutics on pathology. The disease, as it is generally presented in practice, is a pneumonia, and it therefore claims the treatment which is supposed to be appropriate to pneumonic inflammation.

But this is a *non sequitur*, according to the general truth stated in entering on this division of the subject. It does not follow that these measures are indicated, granting that the affection is a form of pneumonia. The only true basis of therapeutics here, as elsewhere, is in clinical experience. Has clinical observation been correct in leading to the conclusion that these measures of treatment are injudicious, at a time when tuberculization was generally thought to be a non-in-

flammatory process, then, assuredly, this conclusion is not upset by proving that the process is an inflammation. The lessons of experience are not to be subverted by changing the name tuberculous infiltration to catarrhal or tuberculous pneumonia.

It is not, then, an unreasonable skepticism, or conservatism, to protest against the adoption of this new view of treatment on mere pathological grounds. We are bound, as it seems to me, not to adopt it until it is substantiated by a collection of facts obtained by experimental observation. We are bound to adopt it whenever it is so substantiated. They who are fairly convinced of the propriety of these measures, as the result of speculation or reasoning, will not be likely to hesitate in employing them; but there are many who cannot at present conscientiously submit them to the test of experimentation.

The pathological opinion stated under the head of causation (and which I believe may be proved to be erroneous), that pulmonary consumption is a sequel of bronchitis, has an important bearing on the treatment. If this opinion be correct, it is a rational inference that it is a special object of treatment to prevent the recurrence of attacks of bronchitis, and that therapeutical measures are to be specially directed to bronchial inflammation. Of those who have had a large experience in the management of the disease in this country, not a few attach most importance to out-of-door life, and enjoin upon patients, not to be deterred from carrying out this hygienic measure by apprehensions of "taking cold." It is common to assure patients that the existence of pulmonary tuberculosis does not render them more liable to attacks of bronchitis, and, if attacks occur, the tuberculous affection is not thereby increased. These statements, which date from the researches of Laennec and Louis, are not in accordance with popular belief, a fact which Niemeyer thinks is very fortunate, considering, as he does, the latter to be the more correct view. This view, there is reason to believe, is based on the supposed causative connection between bronchitis and consumption, rather than on clinical experience.

On the conclusion of Dr. Flint's paper the President introduced to the Academy Dr. James P. White, of Buffalo.

Dr. Alonzo Clark, in opening the discussion, remarked that he did not intend to make a speech, and when the President some time since requested him to prepare a paper for the Academy, precisely the same title introduced by Dr. Flint was proposed. He was as much pleased with the tone of the paper as he was displeased with the views of Niemeyer, being confirmatory of the speaker's clinical observations, first made in 1842.

Reference was also made to the statement of the late Dr. Isaacs, that tubercular meningitis can happen when tubercle is not present.

In alluding to hemorrhage as a cause of phthisis, he was prepared to state, after an experience of a great many years, that a spontaneous hemorrhage happens when tuberculosis is present.

Dr. W. C. Roberts read quite a lengthy paper, showing that scrofulous matter and tubercular deposits were identical in cause, nature, and composition. No distinct lines can be drawn between them, and, clinically, it is not important. In cases of scrofula, tuberculous deposits are almost always present.

The President, in closing, announced that the two stated meetings in November would probably be taken up with the discussion of the papers of Drs. Draper and Flint.

On motion, the Academy adjourned.

Correspondence.

HYPODERMIC USE OF QUININE.

To the Editor of the Medical Record.

Sir—I come before your readers again, but with much reluctance, not because I regard the subject for which I contend as unimportant, or its success as at all doubtful; but because circumstances have of late made it apparently necessary that I should take the field so often, that I am fearing that I am becoming tiresome. May I hope to think that existing events may once more excuse me. In your issue of October 15th, 1870, my neighbor, Dr. E. C. Seguin, appears in a letter, showing that he has felt constrained to again plead for the hypodermic use of quinine, in opposition to my protest against the method as a dangerous and unnecessary abuse of administration. He commences by disavowing any claim on the part of the physicians of the New York Hospital to responsibility for the report quoted by me in my paper on quinine and published under his name. I do not think the profession needed this statement, in view of the fact that there has been no doubt raised by any one of the medical staff of the hospital as to the truthfulness of the doctor's report. Had there even been a question upon this point, it was very easy to settle it by referring to my authority, which I very distinctly said was "published in the *New York Medical Journal* for December, 1867." By referring to that publication the reader will find that this use of quinine was introduced into the hospital in 1866, September, by one of the attending physicians, and that from that time up to the date of the report mentioned, the method had been "a part of the regular practice of the house." I therefore accept the correction, that it was a truthful report of the practice of the hospital, by E. C. Seguin, M.D., &c., and not a report of the same by the medical staff.

This criticism disposed of, I will now answer some of the doctor's queries.

First. "Is there any evidence proving that a moderately acid solution thrown under the skin causes abscess, tetanus, or other grave disturbances?" As to abscesses and grave disturbances my reply is, yes, we have abundant and unquestionable evidence. I will first refer the reader to the doctor's own publication in the *New York Medical Journal* above referred to, p. 224. With regard to his remark, that the occurrence of abscesses in the cases there recorded was a "result attributable to the introduction of insoluble particles along with the fluid," I am obliged to say that he furnishes no proof that such was the fact. On the contrary, he states in the early part of his report that the solution used in the cases recorded, and indeed in the hospital generally, was made and filtered with the greatest care, and further along he informs us that sulphate of morphia may be added to *render the injection less painful* (op. cit.). Admitting this statement as to the care with which the solution used at the New York Hospital was prepared to be true, we are forced to conclude that the doctor's inference, that undissolved particles of quinine or other solid substances were the causes of the untoward results, is a mere theory to support a doctrine which no established facts support, much less demonstrate.

I will next refer the reader to the large amount of additional evidence of the danger attending the subcutaneous use of this acid solution of quinine, which I have collected in my paper on quinine. (See Transactions of the American Medical Association, vol. xx., 1869.) And finally, as very recent evidence against

the use of acid solutions beneath the skin, I call the attention of your readers to an essay by Dr. E. T. Wilson on the subject of the subcutaneous use of morphia. (St. George's Hospital Reports for 1869, p. 20)

This author, educated and trained among the strictest sects of hypodermic medicators, a colleague of the Charles Hunter referred to by the doctor (see his letter), and an enthusiast on the subject, says: "Whatever the salt used may be—whether acetate, meconate, or muriate—it is believed of the utmost importance that the solvent should be water, and water only. When thus used it has never in my hands produced the slightest suppuration or inconvenience; whereas the solutions prepared with acetic acid, and neutralized as recommended by the committee, Charles Hunter and others, have as invariably been attended with present smarting and prolonged tenderness of the punctured part."

Again, at p. 26 op. cit., this same author remarks, under the head of injury to the skin: "When puncture of the skin has given after trouble, this is generally due to the acidity and irritating character of the fluid injected."

If these be truths with respect to *morphia solutions* of an acid reaction, the profession needs not to be reminded that there is every rational probability that the far more acid solutions of quinia are very much more liable to excite serious irritation and inflammation. I will not occupy more of your space with references to the large accumulation of authority in support of the indisputable fact that the introduction of acid solutions, however perfect, into the subcutaneous areolar tissue, is very liable to produce abscess. And yet, in the face of this fact, supported as it is by his own records, the doctor dares to venture to add that, "judging from experience," he "unhesitatingly recommends this method of giving quinine in the following circumstances: 1st, in general hospitals, civil and military, where economy in the use of quinine is a desideratum; 2d, in private practice, in cases of congestive fever, where it cannot be administered by the mouth, or when rapid action is desired; 3d, in private and in hospital practice, for the treatment of neuralgia of malarial origin, in which affection remarkable results are obtained by local injections of quinine, the drug acting in its specific manner upon the system, and locally by *counter-irritation.*" There are few cloaks which cover a greater multitude of sins than the cloak of *experience.* There is no method of practice too absurd; no system of therapeutics too abominable; no chirurgical procedure too violent or even dangerous to prevent its obtaining the support of alleged satisfactory *experience.* Hence, when I hear one hedging his position in by adducing his own experience, which experience ignores the recognized laws of physiology as well as of pathology, I at once challenge his credibility. Of this class I regard all such as urge the hypodermic use of quinine, upon the support of their own *experience,* including especially Dr. Eulenberg. The results of this method of giving quinine are so uniformly attended by the untoward accidents already alluded to, that I should hesitate to accept as reliable any alleged experience of a different character. But in the present instance I am not called upon to reject any such experience, for the doctor, though apparently satisfied with his *experience,* furnishes more than enough disastrous results of the medication to counterbalance any claimed advantage, and quite enough, in my estimation, to condemn the whole system of hypodermic medication with quinine, without going further into the evidence. While he alleges that it is at least an economical method, he is forced to confess that "the very capable apothecary at the hospital is of the opinion that on the whole the treatment results in no saving of quinine." This is as near as may be to the conclusion I reached by examining the records as published by the doctor. (See my paper, op. cit.) Notwithstanding all this, he thinks it *may* be made economical. As to its especial utility in miasmatic neuralgia, claimed by the doctor, I must say that his remark upon its counter-irritant action is both instructive and unexpected. I would respectfully suggest to him that the specific action of the quinine may be obtained upon the system in these cases in a sufficiently prompt, and in a very much safer way than by injecting it under the skin at the seat of the pain; and also that if counter-irritation be indicated, it may be very promptly secured by means not liable to result in the production of abscess at the point of its application. Professional attention is particularly called to this confession of the doctor, as to the local irritant action of the process of injecting, or to the injection itself.

While upon this matter of experience, I will revert to the fact which the doctor is not the first to mention in the course of my journal discussion, viz.: my want of individual experience with the hypodermic use of quinine. This, I am happy to say, is a fact, and it is one of much consolation to me. While preparing a paper on the subject of quinine and its uses in miasmatic disease and exposure, about the close of 1861, I introduced a paragraph containing the suggestion that were one to venture so far he would no doubt find that quinine used hypodermically, after the manner in which morphine was then and still is much employed, acts very efficiently; but that as I had not failed to obtain the desired action of the medicine by other methods, I had not felt justified in making the experiment of using this necessarily acid solution under the skin. Before that paper went to press (it having been published in the Transactions of the Medical Society of the State of New York for 1862) I struck out that paragraph, under the impulse of the reflection that I had no good reason for suggesting a practice that I had regarded of too doubtful propriety to attempt myself. I have more reason every day to feel thankful for the reflection which thus influenced me. I was thereby rendered totally free from any responsibility for the vast amount of needless suffering, to say nothing of the deaths, which have resulted during the last few years from the hypodermic use of quinine. I am unable to see, and I doubt if the readers of the RECORD can see, that I would have been better "qualified to sit in judgment upon" this subject had I produced a few dozen abscesses, or a few hundreds of phlegmonoid swellings, and by chance killed an occasional fellow-creature by giving rise to a traumatic phlebitis, possibly by introducing air into a vein, or even exciting a fatal tetanus. With quite as much reason might we insist that judges and jurors, in order to be qualified to sit in judgment for the trial for alleged crime, should be practised criminals. The question at issue is one which appeals, if I may be allowed the use of the term, to common professional sense, and therefore needs simply the evidence of information to qualify one to sit in judgment upon it. I esteem myself fully competent, by virtue of the evidence, both for and against the method, which I have been at much pains to analyze, to sit in judgment upon it. Should there be any doubt about it in the minds of the profession, I will at once put the question directly to them if the evidence furnished by the advocates and the practitioners of the hypodermic method of medication with quinine is not sufficient of itself to show that it is attended with danger, and a danger too which does not attend any of the other forms of administration.

There can be but one opinion and answer to this question. The doctor apparently thinks that I was quite unjustified in attributing the fatal tetanus occurring in the practice of Dr. Sale, to the quinine used under the skin. He is not the first either to advance this idea. As I have never stated that I believed anything of the kind, no more time need be spent upon this point. In reply to his suggestion that a nerve-fibre might have been pricked, or that some solid particles entered the areolar tissue with the fluid, or that some climatic conditions favored the development of tetanus from very slight causes, I cannot but say that I doubt if the readers of the RECORD will be able to comprehend how the presence of one or all of these conditions is to remove the responsibility of bringing them into action from the totally unnecessary hypodermic syringe. I presume none will venture to assert that a ten, or even a twenty grain solution of the medicine thrown into the rectum, in any of these unfortunate cases, would have produced either phlegmonoid swellings, abscesses, or tetanus, however strong the climatic tendency might have been; and I dare to say that about as prompt, quite as efficient, and as permanent therapeutical effects would have been produced, notwithstanding the doctor thinks that "well-conducted experiments are needed upon this point." Should he deign to institute any such "well-conducted experiments," he may rest assured that they will result in no such disastrous consequences as have been caused by the efforts to convert the subcutaneous areolar tissue into what Divine Providence never intended it to be—a digestive and absorbing organ. In this matter, although the doctor may doubt it, I have had a large and satisfactory experience, and one which is not in violation of well-known physiological truths. I therefore confidently and urgently advocate it; and I am supported by the published results of the experiment of the Scientific Committee of the Royal Medical and Chirurgical Society, though the doctor thinks, or at least says, that these results are "most unsatisfactory," and that they fail "to meet the requirements of modern experimental physiology." They certainly do fail to meet the requirements of *modern experimental therapeutics*. While they fail to meet these modern requirements as to the introduction of the acid solution of quinine under the skin, instead of into the rectum or stomach, the doctor remarks that they say nothing about the danger or innocence of well-made acid solutions thus used. I presume that if ever a *well-made solution* existed, it was that made and used at the New York Hospital by the doctor; and I submit to the unbiassed judgment of the profession, that the recorded results of its use there, though perhaps more than usually favorable, render any qualifying remarks by the Scientific Committee on Acid Solutions under the Skin quite unnecessary. Those results must, in the estimation of every prudent and ingenuous physician, condemn its use.

STEPHEN ROGERS.

249 WEST 42D STREET, Oct. 19, 1870.

ARMY MEDICAL SERVICE.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR—I have read with great interest your Editorial in the RECORD of Sept. 1st, 1870, on "Army Medical Service Abroad," and I consider this an appropriate time to address a few words to your valuable journal on "Army Service at Home." We have just emerged from a great struggle, and Prussia and France are now engaged in a war which may eventually involve the whole of Europe and perhaps America.

My remarks will apply as briefly as possible to the Medical Department of our Army. We were indebted, and our gratitude at the time was extreme, to the personal exertions of three or four Army Surgeons who fought for our rights; and with the valuable assistance of Surgeon-General Barnes, we succeeded in getting the entire management of General Hospitals under the control of the surgeons in charge; thereby, as you justly state, preventing "the placing at the Head of Establishments intended for the treatment of disease and wounds, officers of the Line, who, whatever their other accomplishments, could not be expected to understand the requirements of medical science, and who, with the best intentions in the world, might seriously embarrass the action of the surgeon, as was sadly the case in the Crimean war, &c." But the war ended, and all returned to its pristine barbarism. General hospitals were abolished and post hospitals established. These are under the control of the Post Commander, and so is the surgeon, to all intents and purposes. For instance: "He has no control and cannot fix his hour for sick-call. He has to go round and inspect whenever his commanding officer orders him, sometimes at most inconvenient hours."

He is expected to lend bedding and Hospital property to all and every officer who may send to borrow the same, "and, if he do not, is snubbed; and, at many posts he cannot *go out* for a walk *fifty yards* from the camp, *without permission*." It is true he can *respectfully recommend* this or that to be done; but how often are these recommendations carried out? (I knew a case at a remote post on the sea-coast, where the doctor recommended the men to have fresh meat once a week; but, although there was cattle on the island in abundance, the men had to live on what fish they could catch. The commanding officer was subsequently tried for stealing, &c., but not at the instance of the doctor, and dismissed the service. The doctor preferred a quiet time and a piscatorial diet to quarrelling with such a man.) Now, this case proves incontestably that the Hospital Department should be under the control of the surgeon, unfettered in every way! It is for the interest of the service. Of course there are many officers educated at West Point, and others who have got into the army, in consequence of our late war, who are gentlemanly enough not to interfere with the surgeon; but it cannot be denied many do interfere and make it unpleasant for the doctor, if the doctor asserts his rights as derived from the Army Regulations.

Prussia has within the last two months done wonders against the French Army, which has always been considered invincible on the continent of Europe, by her superior organization and method. Now, allow me to tell you the same good organization extends to her medical service. It is a *distinct branch*. The Surgeon-General is the head. He assigns offices, gives furloughs, &c., and is not under the control of any army officer, neither are his surgeons or assistants. A list of surgeons required is sent to him, and he assigns the number requested to the different posts, as surgeons in charge, and not as is done with us. "Major So-and-So, Surg. U. S. A., or Capt. Assist. Surgeon So-and-so, U. S. A., will report to Lieut. So-and-So, commanding officer, at such a place"—often his *inferior* officer, both by rank and education.

"A surgeon applies for a furlough and he grants it and assigns a substitute temporarily." If, however, a surgeon in charge of a petty post hospital wishes to take a walk or an hour's ride on horseback, I imagine he takes one or the other, and does not have to go to a

commanding officer, who may be and often is a junior, and say, "Please, sir, may I go out for an hour?" In the British army, although they are very severe, the regulations as far as regards the medical department are a dead letter (outside of its own laws and regulations), because the former are not enforced. There is no interference with medical officers. The "officer of the day," called there the "orderly officer," visits the hospital daily, as a matter of form. The surgeons and assistants are supposed to know best when they can be absent for a few hours, and there is never any trouble. During the Crimean war, hospitals were sometimes kept for some hours without fire-wood, in consequence of the scarcity of teams and bad management in the quartermaster's department, but never neglected intentionally by the executive branch. The recent order requiring sick men to be examined by the captain or lieutenant of the company and a certificate signed by one of these officers before the man is brought to the surgeon, to the effect that he has examined said man, "and for *what purpose* and with *what object nobody seems to understand*," places the medical officers in a very unenviable light.

The late case of Dr. Green, of the Navy, who was actually ordered to take a man off the sick-list, and was tried and convicted for refusing to obey an illegal order, is fresh in the memory of all. The army has not come to that yet. The sooner we adopt the Prussian common-sense plan the better. The British government emigration laws require the surgeon superintendent of the ship to sign a certificate that the captain of the ship has treated his passengers well during the voyage, before said captain can receive his pay. When the Dr. was under the orders of the captain, abuses were frequent, and this led the Government to adopt this wise law. It may be said, "If the Doctor be independent, how can he be punished for neglect of duty?" Ans.: "By court-martial."

I must apologize for thus trespassing on your valuable space, but I wished to enlighten you on the minutiæ and take you behind the scenes of the medical service. When you say that American surgery leads the van in military as well as in civil service, we take it as a high compliment, and when you state "that all matters pertaining to the medical care of an army must be entrusted to men educated for the purpose, &c., &c.," you speak truly, and if you could only prevail on the powers that regulate Uncle Sam's affairs in the Dis rict of C. to think as you do, you would confer an everlasting boon on the Doctors of both services.

AN ASSISTANT SURGEON.

ARMY AND NAVY NEWS.

List of Changes of Stations and Duties of Medical Officers of the Army to November 4th, 1870.

SIMONS, JAS., Surgeon.—By S. O. 283, War Department, A. G. O., October 24th, 1870: assigned to duty at Baltimore, Md., as Attending Surgeon and to examine recruits.

HAMMOND, J. F., Surgeon.—By S. O. 126, Headquarters Department of Texas, October 5th, 1870: relieved at Austin, Texas, and assigned to duty as Post and Attending Surgeon at San Antonio, Texas.

ALDEN, C. H., Surgeon.—By S. O. 28, War Department, A. G. O., October 19th, 1870: to report in person to the Commanding General, Department of the Lakes, for assignment to duty.

BACHE, DALLAS, Surgeon.—By S. O. 126, Headquarters Department of Texas, October 5th, 1870: assigned to duty at Fort McKavett, Texas, upon being relieved by Surgeon J. F. Hammond, at San Antonio, Texas.

DAVIS, P. C., Surgeon.—By S. O. 187, Headquarters Department of Dakota, October 19th, 1870: assigned to duty at Fort Benton, Mont. Terry., upon being relieved by Assistant-Surgeon A. B. Campbell, at Fort Ellis, M. T.

BROOKE, JNO., Assistant-Surgeon.—By S. O. 201, Headquarters Department of the East, October 11th, 1870: assigned to duty at Raleigh, N. C., as Post Surgeon, after proper disposition of medical and hospital property at Fort Delaware, Del.

BROOKE, JOHN, Assistant-Surgeon.—By S. O. 208, Headquarters Department of the East, October 22d, 1870: granted permission to delay five days, in compliance with paragraph 6, S. O. 201 C. S. from these Headquarters, after completing disposition of medical and hospital property at Fort Delaware, Del.

SMART, CHARLES, Assistant-Surgeon.—By S. O. 208, Headquarters Department of the East, October 22d, 1870: to report to the Commanding Officer and to the Post Surgeon at Fort Monroe, Va., for duty.

GIRARD, A. C., Assistant-Surgeon.—By S. O. 126, Headquarters Department of Texas, October 5th, 1870: relieved at Fort McKavett, Texas, and assigned to duty as Post Surgeon at Fort Duncan, Texas.

GUNN, G. H., Assistant-Surgeon.—By S. O. 133, Headquarters Department of Texas, October 15th, 1870: assigned to duty at Fort Quitman, Texas, upon completion of duty assigned him in paragraph 6, S. O. 114 C. S. from these Headquarters.

CAMPBELL, A. B., Assistant-Surgeon.—By paragraph 1, S. O. 187, Headquarters Department of Dakota, October 19th, 1870: assigned to duty at Fort Ellis, Mon. Terry., upon being relieved at Fort Benton, Mon. Terry., by A. A. Surgeon Marselis.

KING, W. H., Assistant-Surgeon.—By S. O. 59, Headquarters Cavalry Department, Camp near River Bend, Col. Terry., October 10th, 1870: relieved from duty with this command, and to proceed to Fort Wallace, Kansas, in compliance with telegraphic instructions received from Headquarters Troops in the Field.

KING, W. H., Assistant-Surgeon.—By S. O. 201, par. 1, Headquarters Department of the Missouri, October 26th, 1870: assigned to duty as Post Surgeon at Fort Wallace, Kansas.

COWDNY, S. G., Assistant-Surgeon.—By S. O. 200, par. 2, Headquarters Department of the Missouri, October 25th, 1870: to accompany the detachment of the Seventh Cavalry, ordered from Fort Hays to Fort Leavenworth.

COWDNY, S. G., Assistant-Surgeon.—By S. O. 79, Headquarters Detachment Seventh Cavalry, Camp Sturges, Kansas, October 24th, 1870: to proceed without delay to Fort Leavenworth, and report for duty to the Commanding Officer of that post.

COWDNY, S. G., Assistant-Surgeon.—By S. O. 202, Headquarters Department of the Missouri, October 27th, 1870: leave of absence for 30 days is granted.

ALDEN, C. H., Surgeon.—By S. O. 118, Headquarters Department of the Lakes, October 27th, 1870: will proceed to Fort Mackinac, Michigan, and report to the Commanding Officer of that post for duty.

LIPPENCOTT, HENRY, Assistant-Surgeon.—By S. O. 196, Headquarters Department of the Missouri, Fort Leavenworth, Kansas, October 17th, 1870: will accompany a detachment of the Seventh Cavalry, ordered from Fort Hays to Fort Leavenworth by paragraph 1, S. O. 192, C. S., from these Headquarters.

DELANY, ALFRED, Assistant-Surgeon.—By S. O. 190, Headquarters Department of the Missouri, October 10th, 1870: is granted leave of absence for 30 days on surgeon's certificate.

WIRTZ, H. R., Surgeon.—By S. O. 25, Headquarters of Arizona, October 13th, 1870: will proceed to Drum Barracks, California, and await further orders from these headquarters.

ALDEN, C. H., Surgeon.—By S. O. 120, Headquarters Department of the Lakes, October 31st, 1870: will repair to Fort Gratiot, Michigan, and relieve Assistant-Surgeon S. S. Jessop, U. S. A., from duty at that post. Assistant-Surgeon S. S. Jessop, upon being relieved, will repair to Fort Mackinac and relieve Acting Assistant-Surgeon H. R. Mills, U. S. A.

NAVAL REFORM.—At a meeting of the Alameda County Medical Association, held at its rooms in Oakland, California, October 17th, 1870, the following was unanimously adopted:

Whereas, Of late repeated and persistent insults have been offered our professional brethren in the U. S. Navy, by the authority of the Navy Department, degrading them in rank and position; lessening by example the respect due their profession, and contracting their sphere of usefulness; and

Whereas, In every civilized community throughout the world, save in our Navy, the profession of medicine is considered at least equal in dignity and respectability to any other profession; and

Whereas, In our service the members of the Medical Staff are selected by competitive examination from among the graduates of our medical schools, while the line officers are selected to be educated at the country's expense from among the uneducated boys of the community, by favoritism, by relationship, or, as has lately been proven, by purchase; and

Whereas, Rank and command are distinct ideas, having no necessary connection; there being a recognized necessity for *one* commander in all military operations, to whom the other officers are subordinate for the time being; and

Whereas, If physical courage and personal exposure are the only tests of merit, no corps can show, during the late war for example, a larger proportion of killed by the enemy, by fire, by water, or by the more deadly and insidious foe—disease, than the medical officers of the Navy; therefore be it

Resolved, That we consider the stigma to which they have been subjected as applying to the profession at large, and while it is unremoved we consider that no young medical man having a proper regard to his self-respect can accept an appointment in the medical corps of the Navy and subject himself and his profession to the indignities which the self-constituted and newly-born "Aristocracy of the Line" impose.

Resolved, That we view with pain and sympathy the position of the Senior officers of the Medical Corps, whose long service now renders it impossible for them to resign and commence life anew; and we call upon our Senators and Representatives in Congress to recognize their position as co-equal with the highest in the service, by giving them military rank, such as is justly enjoyed by the Medical Staff of the Army, and by that in the services of each of the civilized nations of the world, together with such increased emoluments and promotions as will recognize their invaluable services to our country, and recompense them for the insults and oppression to which they have most unjustly been subjected.

Resolved, That a copy of these resolutions be sent to each Senator and Representative from this State, and that our delegates to the State Medical Society be instructed to bring this subject before that body for its action.

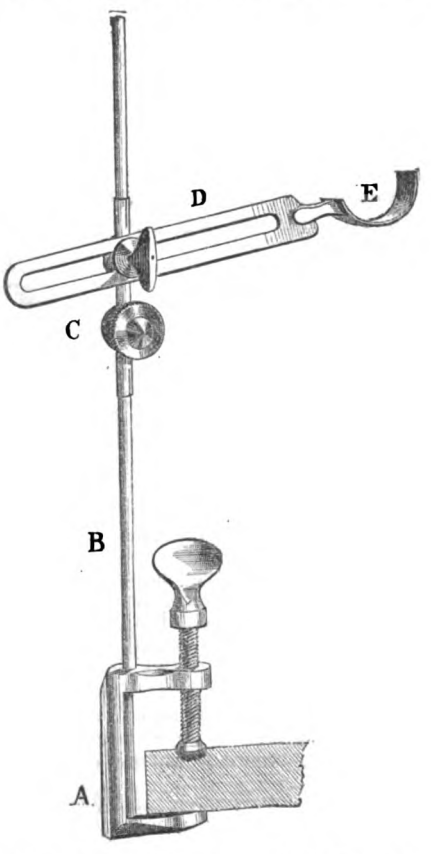
New Instruments.

A HOLDER FOR SIMS'S SPECULUM.

BY JAMES B. HUNTER, M.D.,
NEW YORK.

THE want of a good self-retaining speculum, for use in every-day uterine practice, has led to the contrivance of a great variety of ingenious instruments, several of which answer the purpose tolerably well in a majority of cases. But it frequently happens that nothing will answer quite so well as Sims's speculum; and hence we find many practitioners using their favorite self-retaining speculum where they can, and at the same time keeping Sims's instrument within easy reach for probable contingencies.

After considerable experience with every kind of self-retaining instruments I was able to obtain, I found myself so often thrown back on the good old speculum of Sims, and so often annoyed by the want of a nurse or assistant able to hold it properly, that I was led to devise a simple holder to take the place of the assistant's hand. The result of several experiments was the instrument of which a cut is annexed, and which I have now used constantly for several months with entire



satisfaction. Indeed, I very much prefer it to an awkward or untrained assistant.

The plan of this speculum-holder is so simple that it will be comprehended at a glance. The brass clamp A is attached to the edge of the table on the left-hand side of the operator. In this clamp is fastened a steel rod, B, ten inches long. A brass slide, C, moves freely up

and down the rod, and revolves upon it, being made fast at any point by a screw. In the upper part of this slide is a second screw, passing through a slot in the arm D. The arm is also of brass, and terminates in a curve, E, against which rests the blade of the speculum not in use. It is well to have this curve covered with wash-leather or rubber. The arm moves freely, and may readily be adjusted at the necessary distance from the upright rod, and at any angle to it. I find it generally holds the speculum most steadily when adjusted nearly at the angle shown in the cut; but the position must of course vary considerably in different cases. I expected some inconvenience from the movement of the patient, but practically have found none. I have the patient placed in the usual position on the left side, and then clamp the instrument to the table at the proper place. I next introduce the speculum, and having slipped the holder beneath the free blade, make the requisite tension and fix it firmly in position. Both hands are then free for the use of other instruments.

It will probably be objected to this holder that it does not forcibly retract the perineum, and with the view of effecting this object my first instrument was made to clasp the shaft of the speculum. I afterwards found that if the blades of the speculum formed sufficiently acute angles with the shaft, the perineum was well retracted by the instrument above described and the speculum did not slip out. If the speculum is of the faulty pattern often sold, with the blades at right angles to the shaft, it is impossible to use it satisfactorily in all cases, either with the holder or an assistant. Of the two extremes it is much better to have the angles too acute than the reverse.

134 West 34th St.

Medical Items and News.

Card from the Long Island College Hospital.—It has recently come to our knowledge that a *quack advertisement* has been distributed under cover and stamp of the annual circular of the Long Island College Hospital.

The Regents and Faculty of the College embrace the earliest opportunity to state that this was done without their knowledge, after the circulars had been committed to the news agent for distribution.

They deeply regret the necessity for publishing this card, but duty to themselves and the profession requires that this statement be made public.

Transactions of the Medical Society of Pennsylvania.—The Transactions incorporate the minutes of the annual meeting held in Philadelphia, June, 1870; Address of the President, Dr. W. M. Wallace; Reports of the Committees on Charter and Publication, Vaccination, and Inspection of Drugs; Antidotal Effect of Chloroform on Strychnine, by Dr. W. H. Gobrecht; Dr. R. L. Sibbert's description of a compound craniotomy instrument,—all occupying seventy-six pages of the book.

The remaining one hundred and forty pages are taken up with the reports from county medical societies, some of them containing interesting and practical facts concerning epidemics and endemics of the year, fevers, and other diseases, with notices of deceased members.

The Texas State Medical Association.—The second annual meeting of this Association was held in the city of Houston, on the 15th of June last, and extended over the three following days. This Society numbers fifty members. The following officers were elected for the ensuing year:—*President*, Dr. R. H. Jones, of Brenham; *First Vice-President*, Dr. R. W. Lunday, of Houston; *Second Vice-President*, Dr. W. J. Cocke, of Belleville; *Recording Secretary*, Dr. A. Connell, Jr., of Houston; *Corresponding Secretary*, Dr. D. F. Stuart, of Houston; *Treasurer*, Dr. W. P. Riddell, of Houston.

College of Physicians and Surgeons, New York.—Prof. Thomas M. Markoe now has the chair of surgery in this institution, Prof. Willard Parker having retired. The latter gentleman, however, will hold a clinique every Monday. Prof. John T. Metcalfe has retired from the chair of clinical medicine, but will hold a clinique every Monday at Bellevue Hospital.

Deaths in Philadelphia.—The number of deaths in Philadelphia, in 1869, was 14,786, in a population of about 800,000; one death in 54, or 1.84 per cent. The number of male deaths was 7,644; of females, 7,142; 1,279 died between 1 and 2 years; 1,292 between 2 and 5 years; 1,408 between 20 and 30 years; 1,251 between 30 and 40 years; and 1,020 between 40 and 50 years. There were 1,975 deaths from phthisis pulmonalis; from scarlatina, 799; from typhoid fever, 383; from meningitis, 367; from convulsions, 647; from diphtheria, 175; from croup, 237; from pneumonia, 808; and from cholera infantum, 885.

Seven hundred and ninety were still-born.

Paracentesis Membranæ Tympani.—J. F. Noyes, M.D., Prof. of Ophthalmology and Aural Surgery in the Detroit Medical College (*Detroit Review of Medicine*), reminds us that the operation of puncturing the drum of the human ear comes down from a remote date in history. It was first performed on a human subject, in Paris, by a travelling quack or miracle-worker, named Eli, a little more than a century ago. Willis, Valsalva, and others had previously made the experiment on dogs. Himley introduced it into Germany, and first performed the operation of paracentesis tympani on a deaf person in 1806. It was performed also about that time, in England, by Sir Astley Cooper. In Germany it met with less favor than in France, and was seldom undertaken until quite recently, when, in 1863, Gruber, of Vienna, advised the operation called "Myringodectomy," or the excision of a portion of the membrana tympani, as a cure for impaired hearing and tinnitus aurium.

Prussian Sanitary Arrangements.—According to the New York *Nation*, Professors Esmarch and Virchow have at last succeeded in introducing into the German field hospitals the American system of barracks.

In the war of 1866, Prof. Esmarch endeavored to introduce this barrack system there, but was unsuccessful.

Original Lectures.

THE MASTOID PROCESS IN INFLAMMATORY AFFECTIONS OF THE MIDDLE EAR.

By D. B. ST. JOHN ROOSA, M.D.,

CLINICAL PROFESSOR OF DISEASES OF THE EYE AND EAR IN THE UNIVERSITY OF NEW YORK, SURGEON TO THE MANHATTAN EYE AND EAR HOSPITAL, ETC.

(Read before the American Otological Society, and the Medical Library and Journal Association of New York.)

It is a well recognized fact that the extension of an inflammation of the mucous membrane lining the cavity of the tympanum to that of the mastoid cells, and to the periosteum covering the mastoid process, is a serious matter. Perhaps it is a complication or an aggravation of *otitis media* only second in gravity to an extension of an inflammation of the middle ear to that portion of the dura mater covering and running into the roof of the cavity of the tympanum. In an affection of the mastoid, very fortunately, however, the prognosis depends more entirely on an early recognition of the character of the disease than is the case when an otitis extends to the brain, for, in an early, free, and deep incision through the integuments and periosteum, we have the means of a thorough local depletion, and, almost always, of arresting the dangerous inflammatory process. The early diagnosis of an invasion of the mastoid becomes, then, a matter of much moment. A delay in the recognition of the true state of things allows the extension of the disease to the brain, through some of the numerous foramina which transmit the minute branches of the middle meningeal artery. Pus may also be carried into the circulation through the mastoid vein which passes to the lateral sinus.

At an early period in my medical studies my attention was called to the importance of mastoid inflammation by some cases under the care of my preceptor, Professor Alfred C. Post, and by his recital of several others which had come to a fatal termination as a result of a non-recognition of the dangerous nature of the affection. During the last winter I have again had my attention particularly called to this subject by an unusually large proportion of cases of mastoid trouble, which I have seen in my own practice and that of others, and I have had frequent opportunities of learning that mastoid periostitis is not always fully appreciated.

Some little looking into what has been written on the subject, has convinced me that the mind of the profession would bear a reiteration of some of the more important features of this grave affection as given by the authors and as seen in practice. I will venture, then, to present the notes of a few ordinary cases, with one that is perhaps of more than usual interest, with some points in their diagnosis and treatment, as well as an historical sketch of the operation known as trephining or perforation of the mastoid process.

Case I.—This was under my care at the Manhattan Eye and Ear Hospital, and has already been reported by Dr. C. I. Pardee,* but chiefly with reference to its being a case of *otitis media*, caused by the use of the nasal douche. I saw this patient, who was a man of about thirty-five years of age, soon after the inflammation of the ears had occurred, which was about nine months before he presented himself at the hospital in October, 1869. He was then suffering from a suppurative inflammation of the middle ear, but the amount of pus discharged through the perforation in the membrana tympani was slight. This latter-named state of things, so far as my experience shows, is always to be looked upon with suspicion, if considerable pain or uneasiness in the ear be at the same time experienced. There was considerable swelling of the mucous membrane of the cavity of the tympanum, and the hearing was greatly impaired. He could not hear a watch at all. He was under my care for this suppuration of the ears for eight weeks, when he disappeared, and I next saw him, as just stated, some nine months after at the hospital, when I found his condition had become worse, and that it was alarming. He complained greatly of pain in the head, which prevented him from pursuing his avocation, which was that of a plumber. The auditory canal of the left side was filled with granulations, the mastoid process was red, tender, and painful. Just in front of the meatus there was an abscess, and a small fistulous opening just above the same part. The hearing on that side, as tested by the watch and voice, was completely gone. On the other side the ear was in substantially the same condition as when I first saw him.

I immediately made incisions down to the bone, rather against the patient's will, just behind, above, and in front of the attachment of the auricle. I found no dead or exposed bone, but quite a large amount of pus was evacuated. The patient immediately began to improve. In a few days Dr. Pardee removed a piece of the mastoid structure through the auditory canal, the pain in the head disappeared, the suppuration from the mastoid ceased, the granulations were removed from the canal, and the patient resumed his occupation.

A consideration of some other cases about to be presented will, I think, justify the opinion that in the one just recited there was a narrow escape from brain disease.

The two following cases are from the notes of Dr. David Webster, House Surgeon in the Brooklyn Eye and Ear Hospital, where they were under my care, and are also striking evidences of the prompt relief afforded by timely interference:—

Eliza N., æt. 18, had a discharge of pus from the right ear for two months. The discharge suddenly ceased, and the patient was attacked with severe pain and swelling over the mastoid, which grew worse and worse for several days and caused her to visit the hospital. Dr. Roosa diagnosticated mastoid periostitis, and at once (May 10, 1869) made a free incision down to the bone. No pus was found, but there was free hemorrhage, which was encouraged by the use of warm water. The membrana tympani was found to be removed by suppuration, but there was a slight discharge from the canal. A tent was placed in the wound and a poultice applied over it. May 11, patient has had no pain and has slept well. The tent was reapplied and the poultice continued. May 16, the swelling of the mastoid is gone. There has been at no time a discharge of pus from the incision, but there was a copious one from the meatus. The patient was very pale when first seen, but the administration of iron and the cessation of pain have restored the normal condition. She has not since returned to the hospital.

Margaret O., æt. 48, came to the hospital June 21, 1869. Three months previously she had variola, and in the third week of that disease a purulent discharge began from the left ear. This discharge ceased, when, a week and a half ago, great pain, preventing sleep, set

* MEDICAL RECORD, vol. 4, p. 560.

in. There was found to be considerable swelling and puffiness above the ear, with tenderness behind it, but no swelling. There was great œdema of the eyelids, and the patient seemed to be in great agony. The auditory canal was swelled, but scarcely any pus was found in it. Dr. Roosa made incisions down to the bone above and behind the ear; from the latter pus escaped and a probe passed in a direction slightly upwards, forwards, and downwards into the mastoid cells. The surface of bone about this opening was roughened. The same treatment as in the former case was prescribed. Hydrate chloral gr. xv. was given at bedtime. Dr. Webster saw the patient the next day, when the pain had entirely ceased. June 28, no pain or tenderness. Politzer's method of inflation was practised, and the warm douche used.

July 12. A minute opening about a quarter of an inch from the attachment of the auricle still exists. The probe passes upwards and forwards into a superficial opening in the bone. No swelling, pain, or tenderness about the ear. The membana tympani has healed. Hears the watch 6″.

Case IV.—William G., æt. 39, came to the Manhattan Eye and Ear Hospital, June 13, 1870. In December, 1869, he first experienced a sharp pain in the left ear, which was most severe at night. This pain continued for two months, at the end of which time a discharge occurred from the ear, which has continued more or less until now. Two months later the mastoid process became swelled and tender, and it was opened and poulticed by a physician. A great quantity of pus, as the patient says, was discharged, and the pain, which was severe, was relieved. About four weeks after this the pain in the ear again occurred, and the patient presented himself at the hospital. He presented the appearance of a great sufferer; he was pale and haggard, his hands were tremulous, and his countenance was anxious. He complained of great pain, referred to the depth of the ear and to the head. The mastoid process was red and hot, but not swelled or tender, The auditory canal was exceedingly sensitive. The membrana tympani had been removed by suppuration, and there was a thin coating of pus on the floor of the cavity of the tympanum. Air was forced into the middle ear by Politzer's method, and leeches were applied to the tragus and mastoid. On the next day warm water was frequently instilled.

June 14. The pain in the ear has decreased, but there is more redness of the mastoid. Leeches, to be followed by a poultice, were ordered. I did not see the patient after his second visit, in consequence of my absence from town, until the 20th, when I found fluctuation in front of the meatus as well as great tenderness over the mastoid, with an increase of the constitu ional symptoms. The patient was then admitted as an in-patient, and having given him a dose of whiskey on account of his very shattered condition, I proceeded to make free incisions down to the bone in front of and behind the ear. The bone was not denuded or roughened. A tent was inserted and a poultice, the latter to be renewed every three hours. The patient slept well that night for the first time in some weeks, taking a dose of fifteen grains of hydrate of chloral.

June 28. The patient has been free from pain since. The incisions have nearly healed. There is a slight discharge of pus from the auditory canal. He hears a watch when it is laid upon the ear. His general condition is now very good, and he is discharged at his own request.

It is somewhat remarkable that this patient experienced so many painful symptoms of mastoid disease for so long a time, and yet escaped without disease of the bone. His affection was never more than an affection of the lining membrane, with some periostitis, while in a case about to be detailed, of much less severity, death of the bone occurred, and meningitis, with a fatal result, supervened. I now think that a free incision should have been made over the mastoid when I first saw the patient; although there was then only some redness of the process and no tenderness, the pain being referred to the depth of the ear. In the light of my present experience, in all cases where there is deep-seated pain referred to the *cavity of the tympanum*, which is not at once, that is to say, in a few hours, relieved by leeching and the warm douche, even if the mastoid cells do not seem to be involved, I should consider myself as giving the patient the benefit of a doubt by such a depletion as a free incision will afford.

Experience shows that there is no danger in this procedure, while a neglect to make the incision may be, and I believe often has been, fatal.

We can never sufficiently thank that eminent man Sir William Wilde for having pointed out the virtue of this early incision in periostitis of the mastoid, for it has saved many a life.

These cases are but a type of those which any person who sees much of aural disease must come in contact with; but inasmuch as I know of no positive marks which distinguish them from those which become fatal, I have made them the introduction to a case which had a sad termination, and which, although still obscure, in some respects is sufficiently cleared up to be very instructive.

Before passing on to this I will remark that I saw a case in consultation with Dr. C. R. Agnew, of which I will venture to give the barest outline, inasmuch as it is to be reported in full by Dr. Agnew in the Transactions of the American Otological Society for 1870. The patient, a lady, had a severe pain in the ear for days, from a cold. An eminent surgeon bored into the mastoid with a gimlet and made a bony fistula, which relieved the pain. For years after she had attacks of pain in the ear, attended by suppuration along this fistula. At last, on the supervention of some serious head symptoms, she allowed Dr. Agnew to enlarge the fistula into a free opening by a trephine, which he did in June last, some five or six years after the original inflammation. The patient did well.

The last case which I shall present is one which I saw three times at the request of my friend, Dr. Robert Hubbard, of Bridgeport, under whose care the patient was. The following history has been furnished me by Dr. Hubbard:—

'I was consulted in Dec., 1869, by W. E. S. æt. 38, by profession a mechanic, with good physical development and unexceptionable habits, on account of a severe influenza, from which he was suffering, and which was at that time epidemic in this city (Bridgeport). His mother and one sister I have reason to believe died of tubercular inflammation.

"Hitherto he had suffered no severe illness since the ordinary diseases of childhood, from all of which he made perfect recoveries.

"The attack of influenza was characterized by severe irritation of the whole respiratory system, with marked impairment of the special senses of taste and smell. The auditory apparatus was not at first, however, specially implicated. I prescribed for his 'cold' several times during the acute stage, as an office patient. But he at those visits made no mention of any trouble about his ears. Later he reported that he had lost his cough, but complained of catarrh of the

fauces and nasal passages, for which I prescribed the nasal douche, and gargles made stimulant and astringent by alum, chlorate of potash, chloride of sodium, tannin, etc. To the use of these he ascribed considerable improvement. I then lost sight of him until about the 1st of April, 1870, when he consulted me on account of an annoying tinnitus affecting only the right ear. At the same time he reported that he had occasionally for several weeks immediately preceding suffered moderate hemicrania of the affected side. Inspection showed marked enlargement of the mastoid pocess, which he declared had been at no time the seat of pain, and yielded no suffering under firm pressure. Specular examination showed a moderate degree of congestion of the membrana tympani, and by Politzer's method the Eustachian passage was found to be pervious. The middle ear was occasionally inflated, however, and warm water injections to the meatus externus ordered daily at bed-time, and a blister directed to be applied over the mastoid process. At the same time I continued constitutional treatment by quinine, iron, and strychnia, as he had been the subject some time previously of malarial infection. Under this course the apparent congestion of the membrana tympani disappeared, but the tinnitus was in no degree diminished. At this stage of the case, having met as well as I was able all rational indications, leaving to me only an empirical course, I advised him to consult Professor Roosa, and he advised me to renew the blister to the mastoid region, also to apply a leech to the tragus and repeat it after a stated interval, after which he requested to see him again."

My notes, on seeing the patient, are:—Hearing distance, right side, 2", tested with a watch that should be heard 3"; membrana tympani opaque; no light spot; handle of malleus injected. A very feeble current of air passes into the Eustachian tube. Patient complains of a very annoying buzzing sound in his ear. There is a very slight want of symmetry in the mastoid, no pain referred to it, no tenderness in any part of it; no pain in the ear. Two leeches ordered to the tragus and a blister to the mastoid. One week later I again saw the patient; the symptoms were the same. He had had some pain in the ear one night since his visit. I injected steam into the middle ear, and suggested that leeches be again applied.

(I again copy Dr. Hubbard's notes.)

"These measures were faithfully carried out, but with no good results. The time having come for another visit to Dr. Roosa, the patient called at my office, when examination revealed fluctuation at the summit of the mastoid process, indicating, however, a small quantity of fluid, and attended, as it seemed to me, with too little pain to be explained by the theory of a periostitis. I thereupon advised him to postpone his visit to New York and poultice the tumor for twenty-four hours, and then report again. At his next visit I found the swelling and fluctuation slightly increased, and I freely incised the integuments to the bone, liberating about half a drachm of thick healthy looking pus without disagreeable odor. I then probed the wound, expecting to find denuded bone, but I failed to detect a greater degree of roughness than is peculiar to that portion of the cranium. I advised him to keep the wound open and favor the discharge by poulticing. The discharge for the succeeding few days was little, but resulted in a marked diminution of the tinnitus and a corresponding sense of relief to the patient. He now failed to report to me for about a week, and meanwhile, from lack of attention, the incision healed, and when he presented himself again there was a re-accumulation of pus in much greater quantity than previously. This I evacuated and found it of the same character as before. Thereafter the wound was kept open and the tinnitus ceased, and the patient declared to me and others that he was 'a new man.' From this time my regular attendance ceased until May 12, 1870, when I was recalled and obtained the following history: He had continued in his improved condition until the evening previous, which he was passing in social enjoyment with his family and a brother who was paying him a visit, and, when laughing violently at some burst of humor, he stopped suddenly and exclaimed: 'There, I guess I have laughed too hard, for I have made my head ache.' No further reference was made to his suffering until he had retired to his room at bedtime, when he informed his wife that he was suffering from an intense frontal headache; he also complained of rigors, and passed an uneasy, sleepless night. Notwithstanding a resort to several domestic remedies, May 13, I found the patient still suffering from pain through the forehead and temples; pulse 70, regular, and with steady rhythm; tongue brawny, a thin white fur upon it; intellect clear; skin unusually open, and feeling like the third stage of a paroxysm of intermittent fever, which I confess I was disposed to consider it, inasmuch as he had previously suffered from that disease. I did not consider the symptoms sufficiently clear to indicate anti-periodic treatment, and I therefore temporized by giving the following palliative (a mixture of morph., aconite, and camphor water). May 14th, found him no better. Skin still open; pulse 68, with slight unsteadiness of rhythm, coating still more inflammatory; headache the same; urine rather copious; intellect in the morning clear, but once had requested an imaginary window-frame to be removed from his bed; pupil unaffected, no intolerance of light or sound; temper cheerful. I abandoned the malarial theory, and expressed myself to the friends as apprehensive of basilar meningitis, consecutive to subacute inflammation of the mastoid cells. Ordered an active cathartic, and ʒ ss. bromide of potassium, combined with the iodide. May 14th, P.M. Visited him in consultation with my partner, Dr. D. H. Nash. No relief; on the contrary, an increase of the cerebral disturbances, occasionally delusions and illusions of mind, and mostly of the ludicrous sort; pulse slow and somewhat staggering; *no pain in the ear or its surroundings;* bowels had moved freely two or three times; urine still copious; has had no sleep. Continue the bromide of potassium mixture, apply large blister to the nape of the neck, and give gr. xx. hydrate of chloral, and repeat in 4 hours if necessary. 15th, Had slept about two hours; general condition no better; decidedly humorous in his behavior; double vision, without apparent strabismus, could not read; pulse 60, more irregular; had less pain in the head, or at least he said less about it. Continued same line of treatment, with addition of gr. ij. calomel once in 4 hours. Blister acted thoroughly. 15th P.M. Condition little changed. Prognosis to family—fatal result, qualified by suggestion of possible relief from trephining mastoid process. May 16th, A.M. Patient worse; suggested the counsel of Dr. Roosa; treatment the same. Met him at 9 P.M., with Dr. Nash. Agreed to diagnosis of meningitis, with probable origin from mastoid cells. Determined on free explorative incision upon the mastoid process, and use of trephine if developments indicated it. Accordingly Dr. Roosa made an incision one inch and a half long, parallel with the attachment of the auricle (about one-half inch posterior), down to the bone, permitting thorough examination with the finger as well as with the probe. This means, however, failed on the part of either

of us to discover either necrosis or a denuded state of the bone. After a long search, and when the search and further procedure were about to be abandoned, the probe (in the hands of Dr. Hubbard, R.)—Bowman's No. 1—caught in a little depression, and by considerable pressure passed the external table of the cranium, into the interior of the mastoid portion of the temporal bone, to the depth of one and a half inch, without other resistance than that afforded by the external table. The orifice was now enlarged sufficiently to favor the escape of any pus that might be in the depths of the bone, an opening three-eighths of an inch in diameter, but no great quantity of pus escaped (just a trace, R.). Subsequent examination with the probe revealed a cavity of considerable size, caused by the breaking down of the mastoid cells. (The incision was carefully syringed with tepid water, and the opening plugged with lint, R.) 17th. I first observed dilatation of the pupils, with gradually increasing drowsiness, attended by delirium. This condition continued, with occasional aggravations, until the 19th, when the patient passed slowly into a state of profound coma, and he died without convulsions at 2 o'clock A.M., May 20. No post-mortem examination could be obtained."

I have only to add a few words to the history thus so graphically given by Dr. Hubbard. On the evening of the operation, or the third and last time I saw the patient, I examined the case as carefully as possible, and I found the membrana tympani intact and translucent, no congestion whatever. There was no bulging in any part of its surface. The patient, who recognized me perfectly, and showed that his memory was unimpaired, heard my watch about six inches from the ear—a decided improvement upon the hearing power on the two occasions when I had previously seen him. *There was absolutely no tenderness in any part of the mastoid.* Besides a very minute opening near the superior boundary of the process, which was scabbed over, there seemed to me to be no abnormal appearance in this part, and I examined it very carefully. On probing this minute opening, which was the trace of Dr. Hubbard's incision of some weeks before, there was no escape of pus.

So doubtful did the case seem to me, even with the history of the abscesses which had been opened, that I hardly expected that the free incision which I made would reveal anything abnormal.

There seem to me to be several points in this case which distinguish it from any that I have seen, or that I have been able to find reported, and which should lead us to revise some of our indications for interference with the mastoid in doubtful ear cases.

I. There never was a suppuration of the membrana tympani. A primary inflammation of the mastoid cells or their lining membrane, or of the periosteum in this region, is very rare, as is a middle ear inflammation in which the mastoid becomes involved, without suppuration in the cavity of the tympanum. I have seen one case in which the use of the nasal douche caused an inflammation of the mastoid of one side, without suppuration in any part of the ear, while in the other suppuration of the membrana tympani occurred. But the mastoid inflammation was quickly overcome by the use of leeches.

II. Until the formation of the abscess, the want of symptoms indicating the true seat of the disease. The symptoms were rather those of a chronic inflammation of the middle ear, being detailed by the patient as consisting of tinnitus, fulness, and occasionally slight pain. Certain it is, there was none of the agonizing distracting pain that patients with periostitis usually complain of.

III. The interval of apparent recovery after the evacuation of the pus.

In reviewing the case, the conclusion seems to me inevitable that we had from the beginning to do with a subacute inflammation of the mastoid portion of the middle ear, and which smouldered until the blazing up in the abscess opened by Dr. Hubbard. The origin of this was, of course, the coryza, for which the nasal douche was used. It was perhaps an inflammation of this part, which extended less rapidly than usual to the periosteum and tissues lying upon it, and it was on this account a concealed and dangerous foe. According to a theory of mine the second attack was essentially a new process attacking the former seat of disease, or *locus minoris resistentiæ*,—"the weak spot," as patients say, induced by some exciting cause that is unknown. The integrity of the nerve, up to a late period, is shown by the amount of hearing power exhibited on the evening that the perforation of the bone was made.

HISTORY OF THE OPERATION FOR PERFORATION OF THE MASTOID PROCESS.

Inasmuch as the indications for the perforation of the mastoid process are not very fully set forth in text-books, a very small space being given to this important subject, I have thought that a sketch of the history of the operation, with what seem to be the indications for its performance, might not be wholly uninteresting or unprofitable.

From a monograph on this subject by J. Arneman, Professor in the University of Göttingen, published in 1792, we learn that Riolanus (in 1649 according to Tröltsch) was the first author who inquired into the propriety of perforating the mastoid process *in cases of occlusion of the Eustachian tube*, for the purpose of removing, by injections through the opening, morbid secretions in the mastoid cells and cavity of the tympanum. Rollfink, afterwards, in an anatomical dissertation, published at Jena in 1656, also advocated the operation. J. L. Petit, according to Tröltsch,* was the first who actually performed the operation, which he did by means of a gouge and hammer.

Then we come to Valsalva's case, published nearly a hundred years after the suggestion of Riolanus, which has been claimed by all the authors as a case of perforation of the mastoid, and injection through it of the middle ear. One writer (Tröltsch) states that an otorrhœa was thus cured by Valsalva. I have examined the original passage in order to verify this claim made for Valsalva, and, if I am correct, there is no such claim by Valsalva himself. He simply states that he injected a fistula existing in this part, in the case of a nobleman; with what result he does not say. The passage is found in Valsalva's *Tractatus de aure humana*, edition of 1742, p. 89. The following is the side-note: "*Observatio ulceris processum mamillarem, per quod injecta, statim in oris cavitatem, licet undequaque illasam transmittebantur.*" The passage itself is as follows:—"*Adeoque mitto prolixius confirmare per quondam meam in viro humane observationem, de nobili scilicet viro, ulcere ad processum mamillarem, cum hujus carie laborante in quod quæ injiciebantur, illico ad fauces perveniebant adeoque a tympano, quo per illius processus sinuositates ascendebant, per tubam certe derivebantur*," etc.

I have ventured to translate the passage, with some freedom, but with correctness, as follows. After speaking of the Eustachian tube as a passage to the pharynx, Valsalva says: "I beg to confirm what I have said by an observation made on the living subject, a nobleman, who was affected with caries of the mastoid process.

* Text-Book, p. 470.

Whatever was injected into this ulcer came through to the fauces, from the tympanum to which the injected fluids proceeded through the sinuosities of this process, and from which they passed through the tube."

Valsalva is here demonstrating the function of the Eustachian tube. He makes no claim to have perforated the mastoid, but he simply asserts that he has injected a fistula in the mastoid, and that the fluid thus injected passed into the mouth. I cannot find any evidence in the passage or the context that his patient was cured of an obstinate otorrhœa, as asserted by Tröltsch, so that I think Valsalva must be left out, so far as any evidence from this passage goes, in the enumeration of those who have recommended or performed the operation of which we are speaking.

The surgeon to whom we are indebted for having fairly established opening of the mastoid as a legitimate surgical procedure, is Jasser, a regimental surgeon, who, in 1776, first performed it. His patient was a soldier, who had suffered for many years from suppuration and pain in the ears, which was not relieved by active but judicious antiphlogistic treatment. In this case there was an abscess of the mastoid, and death of the bone,—and thus the operation was performed under indications which any good surgeon of the present day would accept as peremptory. Although Jasser's operation was a creditable one to its author, it has been misunderstood, and classed by Wilde in the list of the same operations performed with such indications as "obstinate deafness."

Arneman, in the pamphlet before alluded to, details five other cases in which the operation was performed, and claims that in only one was there a bad result, and then death ensued. This was the somewhat famous case of Berger, a Danish surgeon, who caused it to be performed on himself, and died of meningitis induced by the operation. He admits, however, that it may be performed without avail.

The second case detailed by Arneman has no more accurate statement as to the pathological condition of the ears of the patient upon whom it was performed, than that *he was wholly deaf in both ears.* The operation did no good, but caused temporary blindness and faintness. In the third case there is also no account of the cause of the deafness: the result was an improvement of the impaired hearing as long as the wound was kept open. The opening was maintained by means of a leaden probe until cicatrization occurred.

The fourth case was that of an old lady, who had lost her hearing from a quartan fever. She had noise in both ears. The process was perforated, and injections of lukewarm water, which passed out of the nostrils, were made. After the injections had been made for four days there was a complete restoration of the hearing (sic), while the openings closed readily.

The fifth case was one of chronic suppuration in the ear, with acute exacerbations. The result was a cure after injections for 12 days.

These statements must of course be taken with some allowance, inasmuch as with the exception of two cases, the first and the last, there is no exact knowledge of the disease causing the symptoms of deafness and tinnitus. But even these show that perforation of the mastoid is not a dangerous procedure, and that when performed under such indications as those in Jasser's case, it is not only a very simple, but a very beneficial operation.

In Frank's* treatise on the ear, which is rather a cyclopædia than a text-book, several cases are alluded to; but here also the indications which direct their performance are wanting, and they are consequently useless as guides to the surgeon.

Arneman, in a style of surgical writing which has now, happily for us with our more accurate knowledge, passed away, lays down the following indications for the performance of the operation. They are inserted here in order that the distrust with which surgeons have looked upon interference with the mastoid process in aural disease may be accounted for.

I. In any case of absolute deafness, or in any case where the impairment of hearing is constantly increasing, and for which all other remedies have been used without effect.

II. When, in case of an ulcer or suppuration of the ear, the morbid material has become collected in the cells of the mastoid, or the cells have become carious. (This is certainly a good indication, and the one upon which Jasser acted.)

III. If the normal mucous secretion has become hardened or collected in excessive quantity.

IV. In cases where pain and noise, which would finally destroy the hearing, have existed in the ear for a very long time.

V. In cases of stoppage of the Eustachian tube not remedied by injections.

The simple operation of creating an external opening for retained pus, and thus preventing its passage to the brain and into the circulation, was thus so distorted from its proper application, that the leading writers seem to have been in as a great state of bewilderment about it as were the English and American surgeons, until a few years since, in regard to the use of the Eustachian catheter. The text-books either mention it to condemn it, or in such a way as to plainly show that they do not realize the true indications for its performance.

So valuable a work as that of Wilde, for example, confounds such an operation as that performed by Jasser with the others quoted by Arneman, which were undertaken because the first operation had been successful, and without any regard to the condition of the ear, but for the relief of a symptom—deafness. We must never forget, however, the great service already mentioned in this paper, which Wilde did by advocating the free incision down to the bone in all cases of inflammation of the mastoid.

In the general advance of our exact knowledge of diseases of the ear, the merits of the operation of perforating the mastoid were again discussed, and it has now been replaced where Jasser first placed it, on a sound basis. Tröltsch,* in 1861, reports a case of acute suppuration in the middle ear with perforation of the membrana tympani, in which he perforated the mastoid with a probe, some days after he had made Wilde's incision with only partial relief.

In such disrepute was this operation at that time, because of the unhappy fate of Berger, who caused it to be performed with no good indications, that Tröltsch confesses that he would have hesitated to undertake this simple surgical procedure with any but the instrument which he employed. The case was a successful one. Eight cases are reported by Tröltsch; that of Petit is considered the first, and Jasser's the second; but Valsalva's injection of a fistula already existing is considered as an operation.

The operation may now be sure to be fairly established and is frequently undertaken, it having been performed by Follin, Turnbull (Philadelphia), Schwartze, Pagenstecher, Hinton (London), Jacoby, Agnew (New York), and by myself since 1859.

* Praktische Anleitung, &c., p. 347.

* Virchow's Archiv, Bd. 21, p. 295.

Jacoby* has especially put the profession under obligations by his valuable report of a case, with the indications for the performance of the operation. Very recently Köppe† and Schwartze report a case of epilepsy caused by retained pus in the middle ear, which was relieved by perforation of the mastoid.

For the performance of the operation the trephine is rarely used. The bone is nearly always found softened by disease, in the cases requiring an opening into the cells, or still more commonly fistulous. A small gouge or the like is then a very good instrument with which to make or enlarge an opening. A writer in the *Dublin Quarterly* for Sept., Colles, reports a case in which he lately did the operation by means of a small elevator. I think it important, before closing the opening with lint, to carefully syringe the opening with lukewarm water, and to remove any granulations or other obstructions in the external auditory canal, which may prevent the free passage of pus.

The site of the opening will usually be indicated by the seat of disease. The fistula is usually found near the summit of the bone where a large cell exists, and next in frequency at the lower portion, where the air-cell is also large. The centre of the bone is usually of a firm non-cancellated structure.

I may be permitted, in conclusion, to tabulate the conditions on which interference with the mastoid seems to be indicated:—

I. The integument and periosteum should be freely divided over the mastoid in all cases in which there is pain, tenderness, and swelling in the part. (Wilde.)

II. Such an incision should also be made wherever severe pain exists, referred to the middle ear, which is not relieved by the usual means, *i.e.*, leeches, warm water, etc.

III. An explorative incision should be made when we have good reason to suspect the existence of caries in this part.

IV. The mastoid bone should be perforated after such an incision wherever the bone is found diseased, or a small fistulous opening should be enlarged. It should also be perforated when we have good reason to believe that there is pus in the middle ear or mastoid cells which cannot find an exit by the external auditory canal.

V. The mastoid should be perforated in the case of a suppuration of long standing, with frequent and painful exacerbations.

ANTERO-POSTERIOR SYMMETRY, WITH SPECIAL REFERENCE TO THE MUSCLES OF THE LIMBS.

By ELLIOTT COUES, A.M., M.D., Ph.D.,
ASSISTANT SURGEON, UNITED STATES' ARMY.

Article VIII.

THE DIGITAL FLEXORS—SPECIAL DIGITAL MUSCLES OF THE HAND AND FOOT—CONCLUSION.

The system of digital flexors on the front of the forearm and palm, and back of the leg and sole, respectively, is double: that is, there is on each limb a superficial and a deep set; the former is perforated and serves second internodes; the latter perforates, and is sent to distal phalanges. These sets are correlative, and symmetrically disposed, with certain interesting modifications to be presently noticed.

The *flexor digitorum sublimis s. perforatus* lies upon the whole length of the forearm in front, covering the deep flexor, arising from the internal condyles and adjacent parts, dividing on the palm into four tendons that serve the four lesser digits—the thumb lacking a tendon from this source. In man, the corresponding muscle of the hind limb, called *flexor brevis digitorum pedis*, is restricted to the sole; but in some other animals it runs part way up the leg behind, taking origin from the outer surface of the tendon of the deep flexor, before this subdivides, instead of from the os calcis, as in man. The flexor brevis (*s. sublimis*) of the foot exhibits in other respects the essential characters of that of the hand; it is superficial, perforated, and inserted into second phalanges. Only, it should be observed, it serves the teleological, not the morphological, representatives of the four lesser fingers; that is, the second–fifth toes; whereas to be strictly symmetrical with the corresponding muscle of the hand, it should go to the first–fourth toes, and leave the little toe unsupplied. It is as if the insertions were collectively shifted one digit outward. But this is palpably a teleological modification in reference to the functional representation of the thumb by the great toe. The comparative anatomist is prepared to meet with such a change by the still greater modifications that the deep flexors show in the distribution of individual tendons. The flexor digitorum brevis, then, of the sole of the foot, is the longitype of the flexor digitorum sublimis of the forearm and palm.

Attentively considering the deep flexor system of the fore limb, we see that each of the five digits receives a tendon that is "perforating," and that goes to an ungual phalanx. These five tendons lie in the same plane; and looking at them after their division at the lower part of the forearm, we might suppose they had come down from a single muscle above. Very likely this is so, in idea; but in effect, the fleshy mass to which these tendons belong has been differentiated into two pretty distinct portions. The smaller, outer (radial) one of these serves a single tendon that goes to the thumb; it is called *flexor longus pollicis*. Its dismemberment is in evident adaptation to free and individual motion of the digit it supplies. The larger, inner (ulnar) mass may be split up to a varying distance above the wrist, but remains, in effect, one muscle with four tendons that act upon the four fingers.

The deep flexor system of the leg and foot—obviously the correlative of the above—is apparently symmetrically subdivided into two portions; an outer, fibular mass, serving the great toe alone, and called *flexor longus pollicis pedis* (or *fl. long. hallucis*); and an inner tibial moiety, giving off four tendons to the four lesser toes; this is the *flexor longus digitorum pedis*. Now it would be at once surmised that the two portions with the same names in the two limbs were the true morphological correlatives, more especially since the great toe and thumb divisions both occupy homologous positions in their respective segments, viz., radial and fibular. But in truth this is not so; the correlation is apparent, not real; these muscles that in man have been pressed exclusively to the service of the thumb and great toe are not morphologically correspondent to each other, but each is the correlative of the common digital flexor of the opposite limb. It is easy to show, not only how this can be, but that it is so.

In the first place, it is necessary to disabuse the

* Archiv für Ohrenheilkunde, Bd. iv.
† A. f. O., Bd. v., p. 282.

mind of an impression that the flexor longus hallucis (i.e., the *fibular* division of the deep flexor system) is always devoted exclusively to the great toe. In fact, this is an exceptional office of the fibular flexor, and represents a modification peculiar (so far as I know) to man. We might have suspected some disguise here, seeing that this fibular (outer) muscle in man afterwards crosses the ankle obliquely, gains the inner side of the foot, and is appropriated to the inner digit (great toe); whereas, in the fore limb, the radial subdivision remains on its own side, and supplies the digit of the same side (thumb*). We have only to go one step downward from man to see an entirely different disposition of the two divisions of the deep flexor of the toes. In the gorilla (*fide* OWEN, *op. cit.*, pp. 58, 59) the tibial flexor "divides into three chief tendons, which are connected with those of the 'flexor accessorius;'" one goes to the fifth toe; one to the second; and one forms a perforated tendon of the fourth toe. The fibular flexor also divides into three tendons, which supply the great toe, the third, and the fourth digits. In some other five-toed animals the tibial flexor may abort and be fastened down before reaching the toes to the tendon of the fibular flexor, which then supplies the four lesser toes. I found this disposition in the opossum, joined with some specialties not necessary to mention here. In the platypus, again, there is no tibial flexor; the large fibular one splits into three tendons to supply the first, second, and fifth toes; the third and fourth are served by tendons of a muscle confined to the sole, but which I take to be a part of the same. We see, then, that there is little constancy in the distribution of the tendons of these two dismemberments; that the fibular flexor is the larger and more important of the two; and that in all animals, as far as known, the general disposition of the tendons is the reverse of that found in man.

The flexor longus digitorum pedis is the correlative of the flexor longus pollicis manûs; the flexor longus pollicis pedis is the correlative of the flexor profundus digitorum.†

In man and other unguiculates, the deep flexors of the digits are reinforced by several accessory muscles, called *lumbricales*. These occur, if at all, in both limbs, and are obvious homologues. With the same general disposition, they present minor modifications in different species. In man, for example, where the distinction of special flexors for the thumb and great toe is well marked, there are only four lumbricales in each member,—the single tendon being unsupplied. Here it will be observed, that while the muscles apparently remain fixed respecting the digits, they are appropriated to non-correlated flexors: viz., to flexor longus digitorum of the foot, and to flexor profundus digitorum of the hand. It seems that they apply themselves to whichever tendons come to the digit they help to move, and should therefore be homologized according to digits, not according to tendons. Thus in the ape's foot, where the flexor longus hallucis and flexor longus digitorum have three tendons each, lumbricales are associated with some of the tendons of both. If we regard lumbricales as parts of the particular muscles with the tendons of which they are associated, in man at least they have not direct homology with each other. The former view is probably the more correct. Further details respecting the lumbricales are unnecessary, after determination of their collective homology. But it may be observed—and the same remark applies to both sets of interossei, and to the individual tendons of both flexors and extensors—that the reference of any particular lumbricalis, interosseus, etc., to its longitype in the other limb, is to be made according to the antitypy of individual digits, *e. g.*, first metacarpal and thumb=fifth metatarsal and little toe, etc. Thus the fore and hind sets are mutually representative in inverse order.

The tendons of the deep flexor of the toes are in man also reinforced by what is called the "*musculus accessorius*." It is far from being a constant muscle in the mammalian series, and is apparently a teleological addition, to counteract, in part, the oblique line of traction of the digital flexor. It has no correlative in the hand. So with the *palmaris brevis*, which is merely a development of a few muscular fibres over the annular ligament.

The rotular and plantar interossei of the foot are plainly the antitypes of, respectively, the anconeal and palmar ones of the hand. It is unnecessary to go into detail here. Identification of individual interossei is to be made upon the principle mentioned above.

There only remain for consideration two interesting groups of muscles: the short special ones that act upon the lateral digits of either extremity. Those of the thumb have received the collective name of *thenar* muscles; those of the little finger are known as *hypothenar*. In the foot no corresponding names seem to have been imposed. They occur, with different digitate animals, under varying conditions. In man, they are more highly specialized, probably, than in any other animal; and individual muscles are more distinctly defined. This is particularly the case with those of the thumb. The gorilla's great toe, however, is more specialized in respect of its little muscles than that of man's is—in fact, it has as many as the human thumb. Through various modifications, and blendings with each other in different ways, we may say, as a generalization, that there are three muscles in each set: a flexor, an adductor, and an abductor. The first of these appears to be the most constant in each of the four digits under consideration; it often, or usually (particularly with the thumb and great toe), consists of two parts, or at least heads, between which passes the tendon of the flexor longus pollicis; it arises from carpus or tarsus close by the articulation of the metacarpal or metatarsal, on which it lies, and passes to the base of a proximal phalanx. The adductors are generally fan-shaped muscular planes, more or less transverse across the palm or sole, lying between lumbricales and interossei, variously, with varying origin, converging to be inserted into the mesial side of the base of a proximal phalanx. The adductor may be differentiated into two distinct muscles, as in the great toe of the gorilla, where they are called adductor obliquus and adductor transversalis; or, in that of man, where they become adductor proper and "transversus pedis." The abduc-

* This fact, and others that follow in the above paragraph, help to show that the thumb and great toe are only functionally or teleologically correspondent, and that the thumb and little toe are morphological correlatives, as declared in a preceding paper.

† In lowest quadrumana the long flexor of the thumb may abort at the wrist; as the long flexor (tibial) of the great toe of some animals does at the ankle; it is then only a little fasciculus from the flexor profundus digitorum. In some other five-fingered beasts, there is no distinction of flexor pollicis; one indivisible muscle sends five similar tendons, one to each digit. Such would be, also, the primitive or typical condition of the long flexor of the toes of five-toed animals. Symmetrical subdivisions of these two would be separation of the fasciculus belonging to the outer tendon in each limb, viz., that of the thumb and little toe. The departure from this that actually takes place in the leg of animals below man is the increase in size of this outer (fibular) division, with corresponding increase of number of tendons, so that other toes besides the little one are supplied. In man, by a curious sort of compensation, the one-tendoned fasciculus changes places, as it were, with the four-tendoned in the leg, thus bringing about a simulated symmetry between the long flexors of the thumb and great toe, whereby they both appear on homologous outer—radial-fibular) sides of the forearm and leg; whereas, not being morphologically correlated, they should appear on different sides of the two limbs, as they really do in lower animals.

tors are generally single, and form the outermost part of the fleshy "balls" of the digits in question; but may be doubled by differentiation, as in the human thumb, whence "opponens pollicis," in addition to abductor proper. Besides these variations, the muscles may blend in different ways, and so be obscured; moreover, they are gradually atrophied, *pari passu* with functional degradation of the digits they act upon; and disappear, of course, with removal of the latter. The foregoing generalizations apply to their fully developed condition.

The thumb and the great toe being teleological correlatives—entirely correspondent in functional position and application—we accordingly find their special muscles developed very nearly symmetrically; and they are more highly specialized than those of either the little finger or the little toe. This is in direct relation to the size and importance of these digits, and their freer movements. They thus correspond better with each other in detail than those of the really homotypic digits do. Thus there are in man three muscles of the thumb and three of the great toe—an adductor, a flexor, and an abductor (the opponens being a part of the latter); and only one—a flexor—of the little toe. But in some lower animals, not only do the thumb and little finger become almost identical with regard to their special muscles, but the great and little toes are also as nearly alike in this respect, so that the difficulty that is apparent in man is taken away. In man, as in all other animals, the identification is to be made with reference to homotypic digits, not to the special muscles that are found in any given case. The special muscles of the great toe, then, are the correlatives of the hypothenar; those of the little toe are the correlatives of the thenar. If it be desired to push the correspondence further, identification of individual muscles may be made by reference to position and function—as of flexor brevis with flexor brevis, etc.

As a *résumé* of the work here concluded, I may say:—That few muscles have not been shown to have correlatives in the opposite limb; that of some of these, now seeming to have none, correlatives will probably be found; that some of the correspondences here laid down are obscure or doubtful; that some others are provisional, subject to further investigation; that most are demonstrably symmetrical, and have been demonstrated so to be.

I am not so sanguine as to suppose that it will not require revision and modification. But however far I may have erred in working out details, I may be considered unfortunate indeed if I have not succeeded in establishing the fact of antero-posterior symmetry. I only profess to have surveyed a field, the existence of which is ignored by some, and denied by others. I hope that those who are convinced that antero-posterior symmetry is no fanciful idea, but a real thing, may be incited to its fruitful cultivation.

No one can be unmindful of a tendency, and possible result, of squaring the effectual operation of 'vital' by that of 'polar,' or other physical, force, usually held to determine forms of inorganic, as distinguished from organized, matter. But a mechanical philosophy of anatomy is certainly not monstrous beside a chemistry of physiology and the possible chemistry of mind. Nor is the gulf between a man and a crystal in the least narrowed by bridging it over. Yet, if reason ever should determine that a man is a masterly mode of molecular motion, and only this, the conclusion would have to be squarely confronted, without hedging in faith. For the measure of faith in reason is the measure of reason in faith: if faithful reasoning fail of truth, the Maker, not the thing made, is responsible.

ADDENDA.

Diarthromere.—A word needed to supplant "vertebra," in the sense attached to this last in these papers. "Vertebrate" may be sufficiently definitive of a backboned animal, but "vertebra," at best a meaningless name of certain 'bones,' is inadequate to express the required idea of a whole segment of an animal constructed upon the double-ring plan, besides being so firmly contracted by custom that the necessary expansion is undesirable if not impracticable. The typical segment—zoönule, or somite—of single-ring animals (articulates) is already called *arthromere*, of which the proposed word is an obvious analogue. Conforming to the proper requirements for such cases, *diarthromere* may be stamped by good usage.

Cephalization.—In this connection, *cf.* DANA, Prof. J. D., *Am. Journ. Sci.*, 2d ser., xxxv., p. 65; xxxvi. (July, 1863), p. —; xxxvii., p. 158; xli., p. 164.

Polarity.—In further consideration of this principle, *cf.* WILDER, Prof. B G., "On the Morphological Value and Relations of the Human Hand;" *Am. Journ. Sci.*, xliv. (July, 1867), p. 44. This "abstract of a paper read before the Nat. Acad. Sci.," which I had not examined before writing, is a concise and lucid exposition of fundamental principles, in the form of twenty-five propositions. Props. 9, 10; 14, 15; 18, 19; 21, 22; are especially pertinent and important. The writer adds four others, of the nature of corollaries, insisting, in particular, upon the inconsequence of the numerical disproportion in the phalanges of pollex and hallux; "the conclusion reached as to the normal position and homology of the thumb . . is confirmed by all purely morphological considerations."

I gladly avail myself of this opportunity to offer the thanks that are due to my friend, Dr. John Winslow, of New York, for his careful revision of proof-sheets, and for other substantial favors he has shown me in connection with the present publication.

Progress of Medical Science.

TWO CASES OF DEATH AFTER RITUAL CIRCUMCISION.—Dr. Schwarz has published in the *Wiener Med. Presse* the cases of two boys, eight days old, who died—one five days after circumcision, and the other twenty-five days after the same operation, both of phlegmonous inflammation and sloughing of the part. Dr. Schwarz deprecates the custom with great warmth, and expresses the wish that it may be laid aside.

LARGE DOSES OF OPIUM IN TETANUS.—Chloral is being extensively tried in this malady. Some statistics respecting its efficacy will be now most welcome. In the mean while it should not be forgotten that heroic doses of opium have, in some hands, been successful. *L'Union Médicale* gives the experience of Dr. Chazarin, who practised for seven years in the French colony of Senegal. He mentions altogether twenty-eight cases, twenty of which, treated by various means, terminated in death. The eight others were submitted to the following treatment: First day, 15 grains of gummy extract of opium in solution; second day, 22 grains; third day, 30 grains; fourth day, 37 grains; fifth day, 45 grains; and so on, increasing the dose each day seven grains if the symptoms did not improve. When 90 grains were reached, the doses were diminished in the

same ratio from day to day. Of these eight patients one only died, and this in consequence of frictions of oil of turpentine imprudently undertaken on the advice of a neighbor. These cases deserve particular attention, though they are not very uncommon, as some analogous ones were published in *L'Imparziale* of Florence in the year 1868. Quinine was, however, in these latter instances added to the opium.—*Lancet.*

Small-pox without Eruption.—An epidemic of small-pox broke out this summer at a place called Limite, near Empoli (Italy). In publishing an account of this epidemic, Dr. Landucci states that several persons presented all the symptoms of the complaint, but had no eruption. Dr. Anciaux, in *L'Art Médicale*, corroborates the cases, and says that he witnessed the same peculiarity whilst the small-pox was prevalent in his locality.

The Liver the Seat of Formation of Urea.—The latest researches upon the place of origin of urea, and especially the beautiful experiments of M. Gréhant, have demonstrated that the kidneys are by no means secretory, but purely excretory, organs for urea. Dr. Cyon, in the last number of the *Centralblatt*, publishes a few facts in the form of a provisional communication, to show that it is probably produced at the liver. The plan of experimentation adopted (in common with M. Istomin) was as follows: The whole of the blood was abstracted from the carotid of a dog, and a portion, after being defibrinated, was transmitted by means of mercurial pressure through the liver. Coincidently three canulæ were introduced—one into the inferior vena cava, the second into the hepatic artery, and the third into the vena porta. The results of careful analysis showed that the blood which had passed through the liver contained a much larger proportion of urea than ordinary arterial blood. In one experiment 100 c. c. of the arterial blood when defibrinated contained 0.08 grammes of urea; but after having been passed four times through the liver, the same quantity contained 0.176 grammes.—*Lancet.*

Cancer Hospital of London.—Dr. Alexander Marsden, in his monograph on "A new and Successful Mode of Treating Certain Forms of Cancer," details some valuable statistics derived from the registers of the Cancer Hospital in London. Scirrhous cancer preponderates in the female breast; epithelial chiefly affects the male in the lip. Of 1,467 persons affected with epithelial disease, 1,022 were males. Of 445 cases in which females suffered from epithelial cancer, the lip was affected in only 5 instances.

For and against Tobacco.—Dr. Blatin, in a work recently published—*Recherches Physiologiques et Cliniques sur la Nicotine et le Tabac*—examines the evil effects on the human system of the use and abuse of tobacco. On the other hand, Dr. J. C. Murray of Newcastle has written an enthusiastic vindication of snuff in his little book on snuff-taking, just published by Churchill and Sons, from which his paper at the Newcastle meeting was an extract: and the marvellous successes of the German soldiers on a diet of black bread, pease-pudding, and twelve cigars a day, has created a strong reaction in favor of the weed, so long abused by the unimaginative as the food of dreamers, and reviled as noxious by those who have no mind to use it.—*British Med. Journal.*

The Alkaloids of Opium.—Professor Roscoe, in commenting at the meeting of the British Association on the interesting researches of Matthiessen and Wright on morphine and codeine, observed that they have thrown a new light on the constitution of these opium alkaloids. Treated with hydrochloric acid, morphine loses one molecule of water, and gives rise to a new base, called apomorphine. This differs in a remarkable manner from morphine, both in its chemical and its physiological actions; being soluble in alcohol, ether, and chloroform, whereas morphine is nearly insoluble; and acting as the most powerful emetic known, one-tenth of a grain producing vomiting in less than ten minutes. Codeine, which only differs from morphine by CH_2, also yields apomorphine on treatment at a high temperature with hydrochloric acid, methylchloride being at the same time eliminated.—*British Med. Journal.*

Antidotal Effect of Chloroform on Strychnine.—To confirm the reputed effects of chloroform on strychnine, and the cases reported in the 12th edition of the *United States Dispensatory*, Dr. W. H. Gobrecht, of Cincinnati, Ohio, reports a case of poisoning, where a young man, aged about 20 years, had taken seven-eighths of an ounce of a saturated solution of strychnia, with crystals in excess, in chloroform, both by inhalation and ingestion, without any other result than complete and prolonged anæsthetization and some temporary subsequent numbness, with no known injurious consequences after two months had elapsed.—*Trans. Penn. Med. Society.*

Labial Thrombus.—Dr. T. G. McPherson, of Beaver Falls, Pa. (*Trans. Penn. Med. Soc.*), publishes a case of labial thrombus the size of a goose-egg, which he relieved by puncture. After turning out the clot, he inserted a piece of soft cotton saturated with a solution of plumbi acetas, removed it and applied a compress, which was also removed next day, no further treatment being necessary.

Tympanitis in Typhoid Fever.—Dr. Senderling, of Berwick, Pa. (*Trans. Penn. Med. Soc.*), has seldom seen annoying tympanitis in this disease since using the sulphite of soda, and in only two cases the last year has he prescribed the ol. terebinth. The rationale of the above treatment of typhoid fever, so far as the sulphite of soda is concerned, he is not prepared to expatiate upon; but, in his opinion, it seems to have a marked effect upon the "materies morbi."

Management of Scarlet Fever.—S. P. Zeigler, M.D., of Carlisle, Penn. (*Trans. Penn. Med. Soc.*), after describing an epidemic of scarlet fever which prevailed in the boroughs of Mechanicsburg and Carlisle, says that he doubts as to the contagious nature of this fever, and bases his opinion on the following facts: 1st. That one member of a family will be attacked with the disease while others will escape, and that the disease does prevail in one section of the town or county, and subsides, to appear again in another section of the town or county quite remote from the first locality, without any direct communication between these districts. 2d. That a large proportion of children, compared with the population, were exempt from the disease. Can a disease so distinctly marked, of such uniform characteristics except in type, be produced from any other atmospheric influence? The treatment he adopted in the epidemic was the following:—Keep the bedroom cool and well-ventilated, sprinkle the floor frequently with a saturated solution of chloride of lime. A mild laxative, if the bowels have not already been relieved, of castor-oil or other mild aperient. Prescribe tonics and stimulants freely, such as sulph. quiniæ, tinct. ferri chloridi, and acidi sulph. aromat., as the case may suggest; chlorate of potassa as a gargle, and externally, to the throat, spts. terebinth. In the latter stage of the dis-

ease, when the tonsils are much ulcerated, and the secretions acrid, he uses the argent. nitrat. gr. xxx. to f. ʒ j. aquæ, as a wash, applied with a camel's-hair pencil or probang.

The percentage of deaths in his practice was 5½ per cent.

INSANITY.—Charles A. Lee, M.D, of Peekskill, N. Y. (*The Jour. of Psychological Medicine*), in his able "Medico-Legal Opinion, Relative to the Sanity of Carlton Gates," asserts that the time will come when insanity will be divided into two grand classes, viz.: *insanity without positive delusion, and insanity with delusion, or affective and ideational insanity.* The present artificial classification of the disease is certainly not in conformity with nature, and the one suggested is really more scientific than one which, by postulating an exactness that does not exist, is a positive hinderance to an advance in psychological knowledge. Until this time arrives, medical experts will have to recognize forms of mental derangement where there are no delusions. The deviations from healthy mental life are innumerable, and the Divine mind can only be pronounced perfectly sound; but let us not make divisions in knowledge where there are none in nature, but regard all present classifications as only provisional. Some writers, for example, would make four kinds of insanity, with reference to the perceptions, the emotions, the intellect, and the will, which, it is stated, may be disordered aggregately or separately; but nature knows no such classification; these forms of insanity run into each other, or co-exist in the same case; the intellect, for example, cannot be deranged without affecting the will; *delusion*, the true test of insanity, may exist in all forms of it, and the same is true of emotional disturbance, etc.

NECROSIS FROM SKATING.—Prof. Moses Gunn, of Rush Medical College, Chicago, Ill. (*Chicago Med. Journal*), recently exhibited four cases of necrosis of the tibia, occurring in boys and young men. One case was remarkable chiefly on account of the large extent of superficial ulceration as compared with the small amount of bone disease. Again, another fact worthy of remark was, that they were so often caused by skating. A young man skates for several hours on a very cold day, comes home chilled through, and goes through the familiar history of necrosis. All of the above cases were young men and boys, and three out of four contracted the disease by skating.

A PECULIAR INFLAMMATION OF THE LOWER LIP.—Prof. R. Volkmann, of Halle (*St. Louis Med. and Surg. Journal*), observed five times a peculiar form of chronic inflammation of the lower lip—*cheilitis glandularis apostematosa*—concerning which he finds no account in literature. All the patients were adults. Three had been suffering from constitutional syphilis a short time before. Two were quite healthy, and assert never to have been syphilitic.

The course of the cheilitis was similar in the five cases, though of different intensity. The lower lip gradually swelled, without much pain, and became hard and firm, so as to give the countenance a coarse, disagreeable expression. The mobility of the lip was much impaired; in one case lost. The swelling extended through the thickness and breadth of the lower lip, and down to its union with the chin. In one case it affected the upper lip about the corners of the mouth. The skin was slightly reddened. In all cases the mucous glands of the lip were swelled to the size of hemp seeds or more, and could be felt through the mucous membrane in unusual numbers and extent as nodular masses. Their excreting ducts were much dilated, some of them large enough to admit a fine probe. Pressure, which caused but little pain, would evacuate from them a turbid mucous or muco-purulent secretion. In three cases abscesses formed. In one case the mucous surface of the lower lip showed from 12 to 15 fistulous openings. In all cases an active catarrh of the mouth and fauces existed. Two cases were extremely obstinate, and left hospital with little improvement; the other three were cured in from 4 to 8 weeks by the internal use of iodide of potassium, mouth washes of chlorate of potassa, and light cauterization of the lip. The disease being an inflammation of the mucous glands of the lip, the author proposes the names of *cheilitis glandularis* or *myxadenitis labialis.*

IMPROVED FORMULA FOR CHALK MIXTURE.—To obviate unpleasant and dangerous souring of chalk mixture, glycerine may be substituted for the sugar, according to the following formula:—℞ Cretæ Preparat., Glycerini, *āā* ʒ ss.; Pur. G. Acaciæ, ʒ ii.; Aquæ Cinnam., Aquæ, *āā* ʒ iv. Rub well together until thoroughly mixed. This mixture will keep during a whole summer. The glycerine exerts a positively soothing effect upon the bowels, as in some degree arresting fermentation.—*Boston Journal of Chemistry.*

SPARGANCINE.—H. Reinsch (*Chem. News*) finds that the seeds of the asparagus berries—dried and roasted—are an excellent substitute for coffee. Of far more importance, however, may be a substance which the author has discovered in the berries, viz., the pigment contained therein, and named *spargancine*—a yellowish-red coloring matter, soluble in alcohol and ether, and yielding, with salts of lead and alumina, yellow-colored pigments.

PERUVIAN BISMUTH.—The increasing price of bismuth, which has heretofore been almost exclusively obtained in Saxony, has caused search to be made for this metal in other countries, which has resulted in bringing Peruvian bismuth into the market. According to Berth, it contains:—

Bismuth	93·36
Antimony, with a little tin	4·57
Copper, with a little iron	2·06

This metal is superior to the Saxon, as it contains no arsenic or sulphur.—*Journal of Applied Chemistry.*

ARTIFICIAL OIL OF BITTER ALMONDS.—The substance known in commerce as artificial oil of bitter almonds is nitrobenzine, $C_6H_5(NO_2)$. It is prepared by adding benzine in small quantities at a time to warm fuming nitric acid; the nitrobenzine, which separates on cooling, is subsequently washed with water. The reaction is represented:—$C_6H_6 + HNO_3 = C_6H_5(NO_2) + H_2O$. —*The Chemist and Druggist.*

QUINQUINA-CHOCOLATE.—Dr. Hengé (*Les Mondes*) has prepared an extract of Peruvian bark so as to possess no unpleasant taste, and this is mixed with pure chocolate paste, so as to form readily-portable, and, at the same time, an agreeable dietetic medicine. The author of this preparation stated, at a meeting of the Central Imperial Society of Agriculture, that it is sulphate of quinine.

AGED PEOPLE.—There are 168 persons in Salem, Mass., over 80 years of age. The oldest is a female, aged 102. Samuel Vogue, of Dudley Township, Henry County, is the oldest person in Indiana, being 107 years old.

CAUSES OF APHASIA.—According to Dr. Julius Sander, of the Royal Charity, Berlin, *emboli* and *thrombosis* frequently give rise to this disease.

CHOREA.—Dr. Mendel, of Berlin (*Am. Jour. Insanity*), remarked in a meeting of the Berlin Psychological Society, that he had observed the favorable influence of Fowler's solution in many cases of chorea.

INFLUENCE OF CANNON FIRING UPON RAIN.—M. Charles La Maont, apothecary at Saint Brieuc, in France (*Jour. of Applied Chemistry*), has published some valuable observations on the influence of artillery firing upon the fall of rain and the force of the wind. During the siege of Sebastopol, soon after the firing commenced the sky became obscured with clouds and a fine rain began to fall, which was sometimes followed by a deluge or whirlwind. The author then proceeds to show how rain could be produced at will by a judicious discharge of artillery. There is some confirmation of the theory in the fact that a violent rainfall has attended the recent cannonading in France.

If this theory is true, meteorological stations with suitable artillery would have been useful as rain-producers, in this country, during the last three months of drought.

TENOTOMY OF THE RECTUS EXTERNUS.—In 80 cases of *exquisite myopia progrediens*, of which the late Professor Graefe took exact notes, as the result of the tenotomy of this muscle, 70 remained stationary after the operation, 4 continued slightly progressive, and but 6 continued as progressive as before the operation.—*Dub. Quar. Med. Science.*

VENEREAL POISON.—Dr. J. Morgan, Prof. of Surgical and Descriptive Anatomy, Royal College of Surgeons, Ireland (*Dublin Quart. Journal*), has observed 1,582 cases of venereal disease in the Lock Hospital, for the last two years, and records the remarkable fact that at this hospital *all* cases of primary sores, as a rule, are sooner or later followed by constitutional signs, often before the patients leave the hospital, and frequently before the healing of the primary affection.

THE OPERATION OF SUB-HYOIDEAN PHARYNGOTOMY.—Langenbeck believes this operation is destined to take an important place among the operations on the larynx. The operation was first described by Malgaigne, in 1835; but Vidal claims the credit of its invention, and asserts that Malgaigne derived the operation from him. The operation was first performed by a surgeon of the French navy, for the removal of a tumor of the epiglottis. Langenbeck performed the operation for the first time in July, 1862, for the removal of a fibrous tumor of the size of an apple, dislocating the thyroid cartilage downwards and to the left side. In 1863 Follin performed the operation successfully on a boy, for the removal of a polypus of the larynx, without tracheotomy. Débroux, of Orleans, in Nov., 1863, performed the operation on a man, æt. 52, for polypus of the larynx. —*Dublin Quarterly Journal of Medical Science.*

NITRATE OF AMYL.—This compound, indicated by the formula $C_5H_{11}NO_2$, and strongly advocated by Drs. Bruntin and Austin in *angina pectoris*, is a pale straw-colored, volatile, inflammable fluid, with an odor like that of over-ripe pears. It is prepared by acting on fusel oil with nitric acid.

CHLORAL.—Sir Jas. Y. Simpson found that sickness is obviated by taking the chloral with lemon juice.

PREMATURE PRESBYOPIA.—Trousseau spoke of premature presbyopia—presbytie prématurée—as one of the most frequent and remarkable symptoms in diabetes. Dr. Fitzgerald, of Dublin, is not aware of this having been noticed by any other author.

GLYCOSMIC AMBLYOPIA.—Dr. Fitzgerald, St. Patrick Dun's Hospital, Dublin (*Dublin Quarterly Journal*), reports a case of glycosmic amblyopia in a diabetical patient, blacksmith, æt. 42, and is inclined to look upon the case as one of atrophy of the retina—a condition described by Soelberg Wells.

M. Testelin (*Annales d'Oculistique*), has published a curious case of glycosmic amblyopia following an injury, in which no hemorrhagic spots were present; the left optic papilla appeared pale and the vessels small.

AN APPROVED VESICANT PLASTER.—M. Delpech (*Jour. de Chimie Médicale*) recommends the following formula for his new vesicant plaster:—Gelatin, 2·09 parts; water, 10 parts; alcohol, 10 parts; cantharidinate of potash, 0·20 part; glycerine, 9·5 parts. The mass should be equally spread on thin gutta percha, a definite quantity being present on each square inch.

ETHER INFERIOR TO CHLOROFORM.—Dr. Charles Kidd, of London, England, editor of the *Mirror of the Lancet*, and author of a work on "Anæsthetics," writes an interesting and instructive letter to the *Boston Medical and Surgical Journal*, in vindication of the claims of American discoverers of ether as an anæsthetic, in answer to those who are constantly publishing articles in English journals upholding the assertions of the late Dr. Simpson. In it the writer asks the subjoined question: "But will the uncompromising logic of facts agree with the pronouncement of Clymer, Otis, and others, of America, that ether is inferior to chloroform, and all the glory is due to the late Professor Simpson?"

POISONING BY WILD PARSNIP.—Lieut. Carpenter, U.S.A., stationed at Ruby Valley, Nevada, recently transmitted a specimen of the "wild parsnip" plant to Dr. Stone, of San Francisco, Cal., and informed him that three men had eaten some of its root; in about half an hour they were seized with unconsciousness. Two of them, who had each eaten a whole root, died at the end of about an hour and a half; the other, who had taken a small portion only, recovered.

The symptoms resembled, with the exception of loss of consciousness, those of strychnia poisoning.

A NEW DRUG.—MM. Rabuteau and Peyre have been experimenting with the root of a plant in use at the Gaboon as an ordeal poison, and locally known as m'boundou or icaja. It will be remembered that it was from this source that the highly valuable Calabar bean was obtained and utilized in medicine. The authors state that, even in very dilute decoctions, it is very bitter, and appears to contain one or more alkaloids, since the aqueous decoction is largely precipitated by iodide of potassium, and also by phospho-molybdic acid. The poisonous effects of this substance bear some similarity to the effects of brucia, but the authors state that, under certain conditions, this poison does not hurt men. Some of the lower animals are readily killed by it; a dose of three milligrammes of the alcoholic extract, placed under the skin of a frog, kills it; and rabbits and dogs are killed by doses of from fifteen to twenty-five centigrammes of the same extract introduced into the stomach.—*British Med. Journal.*

CONTINUOUS DILATATION IN STRICTURE.—Sir Henry Thompson is not an advocate for continuous dilatation in simple cases of stricture, believing that better and safer results are obtained by withdrawing the catheter or the bougie immediately after it has entered the bladder (as Luxmoore recommended) than by leaving it in the urethra from a few minutes to half an hour, as practised by some surgeons.—*Dublin Quart. Journal.*

CHLORODYNE.—In regard to the composition of this popular medicine, the most decisive communication is one from Mr. E. Smith, of Torquay, who made a careful qualitative and quantitative examination of Dr. Collis Browne's chlorodyne, and puts its composition as follows: ℞. Chlorof. ʒiv; morph. mur. gr. xx; æth. rect. ʒij; ol. menth. pip. M. viij; ac. hydrocy. dil. ʒiv; tinct. capsici, ʒvj; mucil. acac. ℥j; theriacæ ad ℥iv. M.—*Pharm. Journ.*

EYE-SALVE IN "GRANULAR LIDS," AND CASES OF CHRONIC OPHTHALMIA.—Dr. John Williams (*Dublin Quart. Journal*), after long experience, speaks most confidently of the following ointment: ℞. Arsenicæ Sulphureti, gr. ij; Unguenti Citrini, ʒij; Axungiæ Preparat. ʒvj. M. Bene.

The upper eyelids should be everted in cases of "granular lids," and about the size of a hemp-seed of this ointment should be applied with a camel's-hair pencil, which must be introduced into the superior palpebral sinus, to the diseased conjunctiva. In suggesting this local remedy he is not unmindful of general treatment.

CARBONATE OF AMMONIA IN PNEUMONITIS.—A. Patton, M.D., of Vincennes, Indiana (*Am. Journal Med. Sciences*), has treated successfully, during the last five years, 96 cases of pneumonitis, upon the exclusive use of carb. of ammonia, using no other medicine excepting that in the congestive stage he has sometimes given 60 drops of chloroform to aid reaction.

If the remedy be given early in the disease, and regularly, in from 5 to 10 grain doses, every two hours, night and day, it will, he says, in almost every case, so limit the exudation process as not only to greatly lessen the amount of hepatization, but to insure a prompt and rapid absorption of the exudation, and occasionally it will entirely prevent hepatization, and terminate the inflammation by resolution.

He also alludes to 213 cases treated in this manner by reliable practitioners in Indiana and Illinois, making altogether 309 cases, all severe and well-marked cases of pneumonitis. In these 309 cases reported there were 8 deaths, or one in 38 cases.

TREATMENT OF TWENTY-ONE CASES OF INFANTILE CAPILLARY BRONCHITIS.—During the winter of 1869–70, Alexandria, Virginia, was visited by an epidemic catarrhal affection, chiefly confined to children, which generally assumed the form of capillary bronchitis. Of the latter, 21 cases came under the care of Dr. Bedford Brown, of Alexandria, Va. (*Am. Journal Med. Sciences*). One of the leading objects was to remove mechanical obstruction from mucous exudation in the air tubes. To accomplish this, emetics of ipecacuanha were used in every case but one. When used freely in the primary or dry stage, the effect in a great measure was to prevent the occurrence of the subcrepitant râle. The sulphate of quinia, in combination with the ipecac, was used in about two-thirds of the cases treated. The febrile action yielded more readily with the quinia than without it. Twenty of his cases recovered.

SYPHILITIC RUPIA.—Syphilitic rupia, accompanied by albuminuria, occurs occasionally, and ultimately carries off the patient. A case of this kind has just occurred in the London Metropolitan Free Hospital, under the care of Dr. Drysdale. Fortunately such cases are rare.

LEPROSY.—This strange malady is stated to be on the increase in the Windward Islands, the "out-islands" of the Bahamas, Guiana, Jamaica, Demerara, Mitylene, Ceylon, Singapore, Penang, Molucca, Mauritius, and the Bombay Presidency; to be decreasing in Sweden, Iceland, Italy, Trinidad, Smyrna; and stationary in Norway, New Brunswick, Barbadoes, Tobago, Scio, and the Madras Presidency.

ELEPHANTIASIS.—According to Mr. Tovey, the Jews of Morocco are thought to preserve themselves from elephantiasis by the use of brandy distilled from raisins, pears, figs, and dates.

THE OPERATION OF NEPHROTOMY AND RENAL LITHOTOMY.—But one case only of nephrotomy, as a means of treating renal calculus, had ever occurred before Mr. Simon's operation of renal lithotomy, at Heidelberg, this year; that was a successful case on the person of the British Consul, at Venice, by an Italian surgeon, in the seventeenth century. Hippocrates mentioned and recommended the operation of nephrotomy in certain cases attended by external swelling, but he has published no cases.

CHOREA.—Hydrate of chloral is highly extolled, in cases of chorea, by a prominent Western practitioner and others. Whether it is permanently beneficial or not, it acts like magic in quieting the unruly muscles, and in allaying the alarm of friends.

TINEA DECALVANS.—Charles R. Drysdale, M.D., of London (*Journal Cutaneous Medicine*), says that we must not be too absolute in any bad prognosis in cases of *tinea decalvans*. Patient application of blisters during a year, and even more, will often be ultimately rewarded by cure of this unsightly disease in young persons, and especially in children. In three such cases lately sent to him for inspection by Mr. Milton, a lengthened treatment by blisters had produced a thick growth of hair, where formerly there had been nothing but wool, or perfect baldness.

CAUSTIC POTASH IN OBSTINATE ECZEMA.—Dr. Chas. R. Drysdale, of London (*Jour. Cutan. Med.*), places great reliance in a strong solution of caustic potash, in many cases of obstinate eczema of the ears and lower extremities—one of caustic potash to two of water. It is a painful application, but the pain ceases on the application of wet sago to the part.

A DISGUISER OF QUININE.—Dr. H. S. Pendon, of Belfast, believes—to disguise the taste—the best plan is to administer quinine in strong hot chocolate.

CARBOLIC ACID AS A DISINFECTANT.—Dr. A. Reeves Jackson, Chicago, Ill. (*Chicago Med. Journal*), finds that many of his patients cannot abide the use of carbolic acid in the sick-room as a disinfectant, for the reason that its odor is vastly more unpleasant and unendurable than most of those which it is used to mask and neutralize.

EFFECT OF BILE ON GASTRIC JUICE.—Dr. R. Burckart has communications on this subject in the *Archiv f. Physiol.* He mixed gastric juice with diluted bile, when the clear fluid became milky, and no longer acted as a solvent on pieces of coagulated albumen. The precipitate was collected on a filter, and washed with strong alcohol. The residue dissolved almost wholly in dilute hydrochloric acid, and had a solvent action on the albumen. The explanation of the effect produced by bile is, that in contact with the acid gastric juice, the biliary acids, and especially the glycocholic, are precipitated, and mechanically carry down with them the pepsine.—*Med. Press and Circular.*

THE MEDICAL RECORD.

A Semi-Monthly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

THE ETHICS OF CONSULTATIONS.

THE danger of interference between physicians while rendering professional services is so great that the most stringent rules are laid down to prevent it. But that these are none too strict every medical man who is brought much in contact with his professional brethren can attest. Particularly is this the fact with regard to the relations towards each other which should be maintained in consultations. Either the ethics of the profession are not sufficiently explicit upon this subject, or the greater number wilfully violate its provisions, for certain it is that there is need in many quarters for a rigid enforcement of discipline.

Consultations are held at the instance of the patient or his friends, or at the suggestion of the regular medical attendant, or both. In either event the position of the consulting physician or surgeon is obviously a delicate one. Whether or not he is really better informed than the gentleman in charge of the case, the very fact of his being called at all removes, generally speaking, all doubts, at least in the mind of the patient, of his eminent fitness to give counsel and aid. The more critical the case the more eagerly do the friends of the patient coax themselves into the belief of his superior qualifications. The attending physician, even if he knows that such a belief is without feundation, so far tacitly agrees with the convictions of the patient that he does not, as a matter of courtesy, strive to overthrow them. The consulting gentleman is thus admitted to the case with a hearty endorsement of all who are most concerned in the proper management of the case, and may, if he is not exceedingly careful in what he says or does, damage very much the estimation in which the family physician is deservedly held. The real purpose of extra advice in difficult cases is to aid the sufferer directly and the attending physician indirectly, the party consulted being only instrumental to that end. If this fact were thoroughly understood and appreciated much bad feeling among different members of the profession would be prevented.

From the peculiar nature of the services which the consulting party is called upon to render, it most generally follows that against them particularly the charges of interference and unjust dealing are made. These charges are founded upon acts which are either intentional or unintentional; both of which, however, work with equally disastrous results against the attending physician. It is a matter for congratulation that the number of those who wilfully violate the trusts imposed upon them is small; but, on the other hand, the unintentional sinners are very many. Of the former, then, we need not particularly speak; they are past reformation, and should be let alone to the full fruition of their dishonest, unmanly, and wicked practices. But to the latter class there is much to be said that may, in the interest of justice and right, be productive of good.

One of the main causes of interference on the part of this special class is a want of caution in their actions before the patient, based upon a false appreciation of their rights. They seem to forget that the absolute rights of a consulting party are far from being many. In fact, they are so few that it seems strange that they should not be known. As before remarked, the real office of the consulting medical man may be summed up under two heads: 1st, advice to the attendant calculated for the greatest good to the patient, directly, and the cause of science, indirectly; and 2d, a policy which shall tend to strengthen the confidence of the said patient or his friends in his medical adviser. Beyond this, under ordinary circumstances, he cannot go without endangering the good standing of the other practitioner.

In order to fulfil his obligation properly, the only necessary communication with the patient should be during the consultation, and always in the presence of the regular adviser. This is the general rule to which there is perhaps but one exception, and that is when the party calling the consultation fails from one cause or another to meet his engagement. Then, after waiting a reasonable time, the consulting gentleman can examine the patient alone, but he should under all such circumstances give his opinion in writing only, and under seal. Those gentlemen who do the largest consultation business in our cities make it a rule that is almost absolute, never to communicate directly with the patients or friends at the conclusion of the consultation, except it be necessary to endorse the physician in attendance. There is really no necessity for doing anything further. Every explanation that it is requisite to make is left to the regular adviser, and if the patients have the confidence in him which they should, they cannot doubt but that he will candidly state to them any new facts of importance which the consultation may have developed. On the other hand, if a consulting party thoughtlessly places himself in a position to be plied with questions he is very sure, contrary to his best intentions, on some

point of trivial importance to be diametrically opposed to the party with whom he has been consulting. Any one must be more than ordinarily acute, who, giving positive answers to such interrogatories, will not differ with another on some point. This being the case, it is obvious that the attendant is the most proper person to reconcile the trivial differences of opinion.

Some gentlemen, in the absence of any agreement with the physician or patient to the contrary, are quite unwilling to understand that their services should cease with the first visit—that after that, unless called again, all responsibility with the case ceases. We have known of some gentlemen who have so far forgotten common courtesy to the attendant that they have not only continued to attend upon the case, but virtually taken such charge of it as to suggest on their own account the proper times of meeting. Such a course is not allowable even if the patient's friends make a request to that effect, unless the physician fully agrees to the measure. If he cannot recognize the necessity he seriously compromises his respect by remaining in attendance any longer. But there are cases in which such a necessity may clearly exist, and which every right-minded person will not fail to appreciate; they are, in a word, such as require special surgical treatment, in the shape of operation, etc. The consulting surgeon under such circumstances becomes the principal, inasmuch as he gives an entirely new direction to the case, and is responsible for the immediate effects of any particular operation. He is supposed to know best when the patient should be seen, and it is properly his duty and privilege to make his suggestions accordingly. But when all the immediate danger is past, it is equally his duty to retire at once.

Again, there is sometimes a very free interpretation of the clause in the Code of Ethics, regarding attendance upon such patients as have been previously under the care of another practitioner. Generally speaking, it is sufficient for the patient to state that he has concluded to change his physician, to make it warrantable for another medical man to give his services. This is a rule which has long ago been sanctioned by custom, and cannot be altered. The patient has a right to change his physician if he so pleases, and having notified him to that effect (after having, of course, paid the bill), is under no more obligations to him. Any physician who would refuse to accept such a case would manifest a species of transcendental fastidiousness that could hardly be appreciated by the most upright member of the Medico-Historical Society. It is another thing, however, when a gentleman is called after having, during the same illness, attended the case in consultation. Under such circumstances he is bound, in honor, invariably to decline having anything to do further with the case. As it is to be presumed that through the practitioner he became known to the family, that the said practitioner perhaps gave him his reputation, he must not in any manner supplant him. If this did not actually occur sometimes, there would hardly appear an excuse for referring to the circumstance as a possibility.

In regard to consultations with specialists, the same rule holds good; but it is so rarely, even unintentionally, violated, that we only allude to it in such a connection in passing. There does not generally seem to be any necessity for wrong-doing on the side of the specialist, as such cases as require treatment at his hands are readily and generously delivered up to him.

Viewing the subject as a whole, there would seem to be no reasonable excuse for misunderstandings as to what is just in the premises. The Code of Ethics is very explicit in its interpretation of the rights of each, and if that is not at hand, every one can easily and safely apply the Golden Rule in its stead. If always actuated by its teachings, there would never be room for misunderstandings in our professional intercourse. In view of the great importance of frequent consultations, this is an end for which we should hopefully and patiently pray.

Reviews and Notices of Books.

A Handbook of Medical Microscopy, by Joseph G. Richardson, M.D., Microscopist to the Pennsylvania Hospital, Secretary of the Biological and Microscopical Section of the Academy of Natural Sciences, one of the Assistant Physicians to the Episcopal Hospital, etc., etc. Philadelphia: J. B. Lippincott & Co. 1871. 12 mo., pp. 333.

Every practitioner appreciates the fact that it is impossible for him to treat disease intelligently without the aid of microscopy. This science has assumed an importance in its relations to medicine and surgery that is second to none other; and by its many important discoveries forces the conviction upon every progressive practitioner that its study is a necessity. It is not to be assumed that the busy practitioner can find the time to become an accomplished microscopist, but it is his duty to be familiar enough with the use of the microscope, to enable him to help himself in the ordinary and necessary examinations of the diseased conditions for which his advice and treatment may be sought. We believe that we are warranted in asserting that the reason why microscopy in its ordinary practical application has not received that attention which it otherwise deserves, is not so much due to a lack of a disposition to master its principles as to the want of the proper treatises upon the subject. Although many excellent works have been published, they have either been too elaborate on the one hand or too abstruse and technical on the other. The student and practitioner has needed a happy medium in the shape of a trustworthy guide, and such a one our author has endeavored to supply. Generally speaking, the directions given to the tyro are not sufficiently explicit and intelligible, the possession of knowledge is taken too much for granted, and the consequence is that the really necessary details of microscopical manipulation, because they are so simple, are left entirely unnoticed. Many a student with a laudable spirit has commenced his studies with these guides, and been discouraged to find in the very first chapter some insurmountable techni-

calities, and has in consequence given up the attempt to proceed farther. We believe that the work before us is calculated to reduce these difficulties to a minimum, and may so far be considered a useful and practical manual. There are, in fact, many necessary details given by the author which we have for the first time seen in a systematic work.

Most of the foreign works on the use of the microscope, although perhaps adapted to the purpose of those students for whom they are written, are not such as Americans specially need. This is particularly the case in regard to the kind of microscopes to be employed, all of them being of foreign manufacture and generally inaccessible to the student of limited pecuniary resources. The instruments of American manufacture are in reality as good and as serviceable as those furnished by English, French, or German makers; and with the advantage of being obtained with but little trouble and comparatively small outlay, are in the main to be preferred for ordinary use with us. Of course we do not mean to affirm that the transatlantic opticians do not excel us in the higher powers, but the possession of such lenses is not necesssary to the prosecution of the microscopical investigations of the practitioner. A lens that will magnify two hundred and fifty diameters is as high a power, if skilfully and intelligently used, as is needed for all ordinary and practical purposes. Dr. Richardson, in his introductory chapter, gives all the necessary information in regard to the American instruments, of low and high priced manufacture, pointing out, in an intelligent and trustworthy manner, the excellences of each. His remarks on the use of the instrument and its accessory apparatus, and his definitions of the technicalities of the science, leave very little if any extra information to be desired. We should, however, be glad to say in this connection, that his description of the method of focusing objects on page 46 is equally practical. The division of the stage, in accordance with the points of the compass, and his allusion to the "upper left hand angle" of the cover as being the first object to look for, etc., is in our opinion unnecessary, as leading to confuse rather than guide the learner. This leads us to speak of the great partiality of the author for long sentences. In his efforts to be concise he will not unfrequently, as in the instance just referred to, introduce parentheses, and make interpolations until a sentence fills an entire page. We contend that the attempts to handle such sentences successfully, are always made with the sacrifice of perspicuity, and they should be especially eschewed by a scientific writer. Our author, in consequence of his parenthetical style, renders himself in many instances liable to be misunderstood; this is the more to be regretted, as in other respects he is as eminently qualified to teach every department of his specialty. But the occasional ambiguity of his expressions is the only fault of his work, and we trust that in the next edition he will be more generous with his periods.

The intention of the writer is to make the work thoroughly practical, and this he has fulfilled. We are much pleased with his system of examinations, and with his methods of solving, with the microscope, the various problems in diagnosis. The chapters on albuminuria and morbid growths are in that respect admirable; we think in these more than any other departments of his work he shows himself to be, not only a thorough microscopist, but a sound and reliable and ingenious diagnostician. With a full appreciation of the value of the instrument in clinical and pathological researches, he takes proper care to inculcate the fallacy of relying entirely upon its revelations. The other facts bearing upon the case come in always to modify the opinion and to complete the diagnosis. The student is led step by step through all his examinations, and there is hardly a necessary point of detail that is omitted. Particularly is this the case with the investigation of the different urinary deposits, which is of so much importance to every practitioner. To these chapters on urinary examination are added some original observations on albuminuria. The study of mucus, saliva, and pus, and the description of the processes by which the author concludes that the corpuscles of each are identical, is interesting, if not conclusive. We believe our author is entitled to the credit of being the first to demonstrate the origin of the salivary corpuscles, and their identity with the leucocytes. By so doing he has helped to corroborate the theory of Cohnheim, of Kiel, in regard to the origin of the pus corpuscle. But these subjects are of more interest to the advanced microscopist than to the tyro.

The necessity and importance of examining the sputa of patients in the early stages of phthisis, are quite conclusively proven in the results attained. We confess to no experience in this line, but are persuaded that the teachings of the author are sound and eminently trustworthy. He bases his diagnosis on phthisis in its earliest stage upon the appearance in the sputum of lung substance, principally fragments of yellow elastic tissue. These latter have generally the mould of portions of the air vesicles. He very ingeniously concludes that the fibres of the air vesicles, being elastic, must break like a thread of india-rubber, with a squarely transverse fracture. The appearance of such fibres he believes to be almost pathognomonic of early phthisis. It is unnecessary here to state that the author describes the processes by which the specimens are made, and gives the very necessary advice to examine healthy lung tissue first.

The examinations of vomited matters, anal, vaginal and uterine discharges, of parasites, and the medico-legal investigation of blood stains and spermatic fluid, are all very practically and clinically considered, proving to the reader that the author is perfectly at home on all.

The concluding chapter, on hints concerning the examination of morbid growths, is the best in the whole work. It points out so intelligently the different recognized forms of tumors, their clinical and characteristic microscopical appearances, and is such a complete résumé of what is at present known concerning tumors in general, that no one who is not an expert can fail to profit by its study. As a whole, we have not seen a work of its sort that in completeness and practical utility can rival it or even compare with it. We predict for it a great and deserved popularity.

The figures, of which there are quite a number, are Camera Lucida drawings by the author.

The following errata should have been inserted:—Page 29, last line, for "achromatic" read "non-achromatic;" page 65, line 26, for "&" read "or;" page 66, line 3, before the phrase "the iodosulphate of quinine," insert the words "two crystals of," from p. 65, line 34, and after it introduce the parenthesis commencing upon line 35 of the same folio; page 197, line 23, for "germination" read "generation;" page 211, line 7, for "muslin" read "linen."

TRANSACTIONS OF THE INDIANAPOLIS STATE MEDICAL SOCIETY, 1870. Pp. 163, Indianapolis.

THE "Transactions" open with an interesting address by the late President, George Sutton, M.D., of Aurora, Ind., on "Man's Power over Nature, and Medicines as means by which he Aids and Controls the Laws of

Life." He remarks truthfully that disease is the natural enemy of man, producing suffering and tending to his destruction. From the Carlisle table of mortality, we know that out of every 100,000 that are born, 14,631 die within the first year, 25,790 of that number within five years,—disease carrying off nearly the whole of this number, pulmonary diseases and diseases of the nervous system and digestive organs being the most prominent. If nature unaided was capable of removing disease, why this terrible mortality?

The remainder of the address is taken up in showing that man, formed in the resemblance to Deity, is a lord over the operations of nature; that man, from the powers delegated to him, is capable of controlling, to a limited extent, the laws of discord around him, as seen in his control over the intellectual, the moral, the physical, and vital laws; that nature prompts him to the development of knowledge, which gives rise to arts and science; that she furnishes him means by which he may guide and control her laws, and that medical science is developing, and is yet destined to be the most grand and noble upon the globe.

Prof. George W. Mears, M.D., of Indianapolis, follows with an instructive Essay on the "Treatment of Puerperal Hemorrhage," which has enlisted from the earliest dawn of obstetric science the ablest minds in the investigation of its cause, diagnosis, and treatment.

Although the author states that we are left to-day with a meagre line of therapeutic agency, we cannot but suggest that the medical profession of the Eastern and Western Hemispheres are constantly instructed by the teachings of such men as Profs. Barker, Thomas, Elliot, Peaslee, Taylor, and others in our own city, and by our English co-laborers, like Barnes, of London. Much, however, is yet to be done in pointing out the best mode for promptly arresting "flooding from abortion," "concealed accidental hemorrhage," "unavoidable hemorrhage," and "post-partum hemorrhage," and this paper—with the appended discussion—is a timely one. In discussing *post-partum hemorrhage* Prof. Mears adds that the most successful application into the body of the uterus is a lump of alum rubbed over the surface from which the placenta has been detached.

The ten elaborate papers which fill up the remainder of the beautifully printed volume, are creditable to the progressiveness of our Indiana friends.

This Society has 488 permanent members and 27 honorary members. The present officers are as follows:—

President, R. N. Todd, M.D., Indianapolis; *Vice-President*, I. N. Rosenthal, M.D., Fort Wayne; *Secretary*, G. V. Woolen, M.D., Indianapolis; *Assistant Secretary*, W. J. Elstun, M.D., Indianapolis; *Treasurer*, J. H. Woodburn, M.D., Indianapolis; *Librarian*, A. W. Davis, M.D., Indianapolis.

THE NUMBER OF STRICTURES IN ONE URETHRA.—Sir Henry Thompson tells us that John Hunter records an instance in which he met with *six* strictures in one urethra. Lallemand mentions one with *seven;* Colot saw one with *eight;* Descamp says there are rarely more than two, but that he has seen *four* or *five;* Boyer thought three could exist together. A case is reported by Leroy D'Etiolles, in which he found *eleven;* but since this is sometimes quoted as if it were a *post-mortem* observation, it is necessary to state that this number rests only on the evidence afforded by the passage of an exploratory bougie. Rokitansky speaks of *four.*

This distinguished author assigns the first place, in relation of frequency of occurrence, to the stricture which occurs at the posterior part of the urethra.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY

STATED MEETING, OCT. 26, 1870.

DR. J. C. HUTCHISON, PRESIDENT, in the Chair.

CONCEALED UTERINE HEMORRHAGE.

DR. FINNELL exhibited on behalf of Dr. Wooster Beach the uterus of a woman eight months pregnant, who died of concealed hemorrhage. She had been seized during the night with pains simulating those of false labor, for which an anodyne was administered by her physician. Six hours later the pains becoming very severe, the attendant was again called and found her flooding violently. Death occurred fifteen minutes afterwards. The case became one for the investigation of the coroner, in consequence of a charge of neglect against the physician. At the autopsy the uterus was found to contain an eight months' fœtus; the membranes were not ruptured and were intact, but the placenta was entirely detached, its uterine surface laying in a large blood-clot. The point of placental attachment had been on the left side of the fundus. No cause for the accident had been assigned. The placenta was not preserved. The uterus was at some points scarcely more than two or three lines in thickness.

DR. SHRADY, in view of the possibility of diseased placenta being the cause of the premature separation, asked if the organ had been examined microscopically.

DR. FINNELL answered in the negative, and regretted that the organ had not been preserved for that purpose. In regard to the management of such a case, he believed it would have been best to have ruptured the membranes and delivered the child at once.

DR. SAYRE was of the opinion that large doses of ergot would have been serviceable in inducing rapid contraction of the uterus.

DR. WHITE, by invitation of the President, remarked that the physician could hardly be blamed for his management of such a case, as there were no well-defined symptoms of uterine hemorrhage save those which belonged to alarming syncope. The pains were very apt to simulate those of false labor. He did not think it would be advisable to make a rapid delivery, and empty the uterus suddenly, before uterine contraction was induced, either by a firm bandage and pressure, or by ergot.

DR. EAGER thought it was quite evident that the patient was moribund when the physician arrived, and that no time was allowed for any manipulations.

On motion the uterus was referred to the committee on microscopy.

PERFORATION OF ILEUM—STRANGULATED HERNIA.

DR. MASON presented a perforated portion of the ileum of a woman fifty years of age. She had been seized with the symptoms of strangulated hernia, and after considerable effort succeeded, as she thought, in reducing the gut. There was no great pain complained of, but suffering from soreness of the abdomen she took in the course of the next twenty-four hours a large enema. A few hours after she sank and died of exhaustion. On opening the abdominal cavity the peritonæum was found to contain the contents of the intestine. The perforation from which they took place was caused by the separation in the strangulated portion of a small slough at the juncture of the mesentery. The accident was the result of the injection.

VESICAL CALCULI.

Dr. Henschell presented two oblong phosphatic calculi discharged respectively at different times, per urethram, from a female. The patient first consulted him in consequence of what she supposed to be uterine disease, but the general symptoms being those of urinary calculi, the bladder was examined. The diagnosis was made and treatment by alkalies commenced. The point of interest centred in the absence of the metallic click, which the exhibiter explained on the supposition that a diverticulum existed.

OSSIFICATION OF CHOROID.

Dr. H. Knapp reported that the microscopic examination of the two eye-balls, which he had presented at the last meeting, fully confirmed his views on the origin and extent of ossification in the eye.

He then demonstrated another eye-ball which he had removed three weeks previously for chronic iridochoroiditis, having caused sympathetic inflammation in the other eye. The abrupt termination, in the region of the ora serrata, of the hardened posterior portion of the globe was distinctly felt before the eye was removed. Upon this symptom was based the diagnosis of "ossification of the choroid," starting from, and limited to, the chorio-capillaris, probably with a transverse septum behind the lens. The anatomical examination of the globe confirmed this diagnosis fully, and showed plastic inflammation of the ciliary body and iris, to account for the production of the sympathetic affection in the other eye.

CANCEROUS DISEASE OF MESENTERY.

Dr. Thomson presented an abdominal tumor removed post-mortem from a young man, aged twenty-five, to whom he had been called to decide as to whether operative procedures were advisable. There was considerable tympanitis, but by gentle manipulation, a tumor about the size of an orange was detected just to the left of the umbilicus, deep-seated and attached at its base to the spinal column. It seemed to be continuous, on percussion, with the line of the spleen posteriorly. The patient had complained of constant pain in the back for over eighteen months, and at times, especially in the latter part of the day, it became so severe that it caused emesis. There had been no trouble about gastric or intestinal digestion, neither was there emaciation. Besides his pain in the back he had also severe pain in the head of the penis, and would feel at times as if the organ were literally packed in ice. Occasionally the flow of urine would be arrested in consequence of this pain. Again much pain was complained of in the left groin, in both hips, in the balls of the feet, in the breast, and between the shoulders. The diagnosis of cancerous tumor was made, involving probably the left kidney. Some two weeks afterwards the patient rather suddenly commenced to sink and died, exclaiming in his agony, "Oh, my poor shoulder!"

At the autopsy the abdomen only was opened. The peritonæum was healthy in every part, but its cavity was filled with blood. The tumor, rounded in shape, was discovered firmly attached to the left sides of the last two dorsal and first lumbar vertebræ, involving the region of the psoas muscle and extending down into the pelvis. On the opposite side of the spine was a chain of enlarged ganglia filled with softened material. On microscopic examination these ganglia as well as the tumor, which was in reality nothing more than an enlarged lymphatic gland, were found made up of collections of large and irregularly shaped cells. The source of the hemorrhage was not discovered. The point of interest was the wide radiation of the pain.

ANEURISM WITHOUT DILATATION—RUPTURE, ETC.

Dr. Janeway presented, on behalf of Dr. McCann, the heart and annexa removed from a man aged forty-five, who dropped dead while eating his dinner. The pericardium was found filled with blood which had escaped through a small rupture half an inch in length, situated on the right and posterior surface of the aorta, just as it passes beneath the pericardium. Around the rent were evidences of chronic endo-arteritis. There was no dilatation of the artery in this case, this being the third or fourth specimen of the kind that Dr. Janeway had seen.

Dr. Thomson in this connection referred to a man who had died in coitu. There was a rupture of the aorta involving the left coronary artery. In that case there was no aneurismal dilatation whatever.

Dr. Buck exhibited a specimen of aneurism which illustrated the effects of treatment by the passage through its cavity of a fine silk thread. By the special request of the exhibiter the details of the operation, appearances of the specimen, etc., are for the present not entered upon the minutes.

Dr. Jacobi lastly exhibited, on behalf of Dr. Wooster Beach, a heart, the seat of what were believed to be numerous cancerous tumors in the substance of the ventricles. By request it was referred to the Committee on Microscopy.

The Society then adjourned.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Adjourned Anniversary Meeting, Nov. 7, 1870.

Dr. John R. Van Kleek, in the Chair.

After the reading and approval of the minutes, the President *pro tem.* read the following farewell letter and synopsis of the business of the Society for the past year from the President, Dr. George T. Elliot:—

Gentlemen:—At the close of my second term of office the time has arrived for me to say farewell, and to return my thanks for the kindness and sympathy you have shown me during my illness, as well as for many other tokens of good feeling during my administration.

It is pleasant to know that the position of the Society has been strengthened, its numbers increased, and the benefits of its labors laid regularly before the profession through the admirable stenographic reports of Dr. Winslow. Such reports are often invaluable, securing for the many the benefits of the unpremeditated utterances of men of experience, who lack the leisure or inclination to write or publish for themselves.

I do not see in what way the working plan of the Society can be greatly improved. Its founders have left little to be done in that respect by their successors; and especially have they provided against an infinite waste of time and temper by the admirable custom of referring all business matters to the Comitia Minora.

The custom which I introduced, and have carried through the past year, of regularly holding an adjourned meeting, in addition to the monthly meeting, seems to me deserving of being maintained, while it is not probable that time could be found for more, in deference to the claims of other societies. I have had no difficulty in arranging for papers for the meetings; and I am happy to express my conviction that a steadily increasing interest is being felt in the city both for papers on scientific and practical subjects, and for the debates to which they give rise.

Therefore, with every prospect brightening for the

increasing activity and usefulness of the Society, and with the sincere hope that it may not only increase its reputation, but may stimulate its fellow societies throughout the land, there only remains to wish you all individually happiness and success, and to submit the following report of the past year's work:—

November Meeting.

Address by the President.

Announcement of Committees.

Paper by Dr. Jacobi, on "The Theory and Demonstrations of the New Hypnotic, Chloral."

December Meeting.

Paper by Dr. Hammond, on "The Physiological Effects and Therapeutical Uses of the Hydrate of Chloral."

Paper by the Vice-President, Dr. Thomas, on "The Induction of Premature Delivery as a Prophylactic Resource in Midwifery."

Adjourned December Meeting.

Paper by Dr. John C. Peters, on "Arterial Sedatives."

January Meeting.

Paper by Dr. Clymer, on "Some Points in the Clinical History and Pathogeny of Locomotor Ataxia."

Adjourned January Meeting.

Paper by Dr. William A. Hammond, on "Spinal Irritation."

February Meeting.

Paper by Dr. C. R. Agnew, on "Ophthalmic Therapeutics."

Adjourned February Meeting.

Paper by Dr. Foster Swift, on "The Pathology of Eczema."

March Meeting.

Paper by Dr. Austin Flint, on "The Prognosis in Chronic Diseases of the Heart."

Adjourned March Meeting.

Paper by Dr. William R. Whitehead, on "Reproduction of Bone."

April Meeting.

Remarks by Dr. Austin Flint, Jr., on "The Physiological Effects of Muscular Exercise."

Adjourned April Meeting.

Paper by Dr. J. C. Nott, on "Intra-uterine Medication."

May Meeting.

Paper by Dr. W. T. Tusk, on "The Theory of Diabetes."

Adjourned May Meeting.

Second paper by Dr. J. C. Nott, on "Intra-uterine Medication."

June Meeting.

Paper by Dr. William B. Neftel, on "The Action of the Galvanic Current upon the Sympathetic Nerve."

September Meeting.

Specimen of Diverticulum of the Intestinal Canal, presented by Dr. Finnell, with remarks.

Maps of the Course of the Different Epidemics of Cholera, presented by Dr. J. C. Peters.

Nomination of Officers.

Adjourned September Meeting.

Paper by Dr. Austin Flint, Jr., on "The Influence of Long-continued Muscular Exercise on the Composition of the Urine."

Number of new members admitted during the year, 33.

Average number present at each meeting, 80.

With the reading and approval of the minutes of this adjourned meeting, the Anniversary Meeting was concluded; and Dr. Van Kleek resigned the chair to Dr. Jacobi, whom he introduced as the President elect, the session now becoming the regular

STATED MEETING, NOVEMBER 7, 1870.

DR. ABRAM JACOBI, PRESIDENT, in the Chair.

THE PRESIDENT proceeded at once to read an elaborate and exhaustive paper upon *Craniotabes*, illustrated by specimens and drawings. Any just abstract within our limits would be simply impossible, but the paper will immediately appear in full in the November number of the *Journal of Obstetrics*. After completing his review of this subject, he remarked as follows:—

ADDRESS OF THE PRESIDENT ELECT.

In the foregoing, gentlemen, I have not confined myself to simply a few introductory remarks. If I were more eloquent, I should have tried to thank you in more appropriate terms than I shall probably be able to command, for the honor you have conferred upon me in electing me your President for the ensuing year. As it is, I have considered it my duty to contribute something to the scientific ends of the Society, the more so as there are only eight or nine stated meetings during the year designated for that purpose, and for the further reason that you have deemed proper to effectually seal my lips for the next twelve months.

Still it would be improper not to express the thanks I feel for the honor you have given, and which I certainly had no reason to expect, inasmuch as I *have* had the pleasure of being chosen your Vice-President a few years ago.

I will not speak of the customary surprise at my election, nor will I say that it was undesired or unhoped for. The honor of being the President of the largest medical society in the United States—this society being, moreover, the County Medical Society—is certainly worth craving and hoping for; and therefore I trust that you will appreciate my thanks, as I your good will.

There is only one duty left to me this evening—just to give you my ideas on the position this Society ought to hold, and its duties in relation to science, to its individual members, to the public, and to the body politic. Do not fear I shall be too prolix on these points. But I think the Society justified in wanting to know the views of its officers on the most important matters.

The stated meetings of this Society are principally dedicated to the reading of scientific papers and to their discussion. I believe that, as long as I have been acquainted with the working of the Society, its efforts compare favorably with the merits of other societies. Some of the papers I remember to have listened to were far above the average, and replete with new ideas and fertile suggestions. But we suffer from one circumstance, which has crippled our progress, and detracted from the scientific value of our exertions. We have good physicians and surgeons, we even have eminent men in many branches of the exact sciences. But we have, with very few exceptions, no profession

of learning, no men who can afford to give their whole time to study, to independent work. The great names of medical science are all European. And Europe would be very willing indeed to receive us amongst the best of her own. The Nott and Gliddon, the Morton, Silliman, Wormley, Flint, the Elliot and Thomas, the Gross, Peaslee, and others, are so well appreciated on the other side of the Atlantic that America, while proud of what has been attained under the most difficult circumstances, ought to look for means to improve her scientific standing and usefulness.

It has long been a petted idea of mine, that the County Medical Society will, one day, help in solving the question how science can be delivered from the weight of daily mechanical toil, which so impedes the freedom of thinking and working; that it will aid in creating institutions that shall be worthy of the country we live in, and afford the means to such as by nature are destined to become the teachers of their fellows, to follow the inspirations of their genius without the spectre of necessity driving them into the hardship of daily mechanical work. Such men as Europe possesses by the score are absolute requisites for us. It is true that electricity and steam have made the world one country, and that no secrets are known in the republic of science that are not common good. But the life of civilization is reciprocity; it will not do always to take without giving. We have the greatest territory, the longest railways, the largest steamboats, the most extensive telegraphs, the boldest bridges and buildings, and the smallest original scientific literature. The wants are clear. Let us all do our share in elevating our science, ourselves, and each other.

I believe that a large number of our members will agree with me in one point concerning the composition of this Society. Not everybody can be a great genius; there are but few such; average intellect is what most of us have to be satisfied with, and beyond the gifts of nature we cannot possibly go, neither we nor the members of any other profession or society. But there is one thing which can always be of the highest order, because it but partially depends on intellect and education. It is wisdom and morals. While we have to be satisfied with the mental powers we can command amongst us, we must command the morals, not of the average, but of the best. I speak in my own name, and in that of my colleagues, when I ask you to help us in gaining the co-operation of the best men that can be found, and in keeping out or driving off such as ought not to belong to us. We ought not to believe that any profession ennobles a man who is not worthy to enter. There is no trade, or profession, that can be protected from unworthy intruders. If there is any profession, however, which deserves not to be thwarted by them, it is ours.

If it must be our object to obtain the good-will and active co-operation of good men, I entreat you, gentlemen, to help your Board in enlisting those amongst our numbers, whom we see here but rarely, for active work. Some of the best men of the city, who are members of our Society, are absent more frequently than the interests of the Society will permit. To whom much is given, from those much is required. If the dignity, the solidarity, of the medical profession of the city and country is to become a fact, not one member ought to refuse to go on duty. There are always more men willing to listen and learn, than there are such as are able and willing to teach. I do not make this remark with regard to such of our members only as have gained a well-deserved reputation by life-long work, but also with special regard to those younger men, in whose brains the future of American science is getting prepared, who are given to studies of a special nature and to exact investigations.

Only those who do their full duty to themselves and their fellows will have a right or a chance to modify our relations to the public and also to the body politic. I do not speak of the individual relations of the physician to his patients—rules cannot be given in regard to these—but of his relations to them in matters of common interest, for instance, public institutions. We live under peculiar circumstances. Our political organization is such that our theory is frequently better than our practice. We have the best constitution on the globe, a constitution framed by wise men, and adapted to wise and prudent men, and at the same time a larger class of ignorant and illiterate fellow-citizens in the territory over the United States than any other civilized, even monarchical, country. We have the good republican rule of electing the best men to offices,—and they say it has happened that a bankrupt mechanic has turned the moral and mental leader of a large community, or an incompetent tradesman all at once a wise statesman, the savior of his country politically. The remedy will be found in a civil-service bill, the necessity for which is so generally felt that it is a Republican Senator and a Democratic Representative who have undertaken the task of securing it.

In our public relations, generally, we have to deal with similar difficulties. As a country we are young, upstart, and are suffering from all the incongruities of upstart communities. The great process of growth, helped by unbounded appetite and good digestion, is not yet finished. Society is by no means in a steady condition. As there are marble palaces and hovels in close proximity, so we have sudden wealth and young education—very young and unfinished education—under the same roof. Society is not always ruled by the best; it is usually controlled by the powerful and the ambitious. The greatest and most uncontrollable power is money; no matter whether it is made by brain-work, industry and saving, or by blockade running, shoddy, or stock-jobbing.

The public institutions, in which the medical profession take a lively interest, are controlled a great deal by money, family, clique, or political influence. They ought to be the subjects of the closest attention on the part of the profession as such. United efforts in that direction will prove efficient; for, certainly, in every board, no matter how composed, there ought to be some members willing to do the best. We ought not to despair of human nature to such an extent as to believe that there should not be some who would be glad to be guided by the judgment of experts rather than by their own inexperienced intuition. I have always thought that the County Medical Society, by studying the affairs, the statistics, resources, results, merits, and shortcomings of our public institutions, would work in just the proper sphere, and for the benefit of our fellows and of science. There is no medical community which has more talent, and not one which has more authority. It is our duty as well as right. The Medical Society of the County is, moreover, through the State Medical Society, intimately connected with the State and its politics. I know the time will come when the opinion and advice of the County Medical Societies and the State Medical Society will be asked for in regard to one most important matter—I allude to medical education. The material wealth and power of the country had its best help in decentralization; but private means and competitive efforts do not appear to be able to afford the millions, collect the genius and talent, and create the museums and institutions worthy of seats of learning, such as Europe boasts of by the dozen. It

the time will come for such progress, the task of advice and practical interference will be with the County Medical Societies.

I throw these hints out, believing in their being correct, requesting the gentlemen to keep them in view; and finally requesting you to believe that, whether they are wrong or right, I shall be but too willing to work with you for our common interests.

NEW MEMBERS.

The President announced the admission to membership of Drs. Henry Griswold, Charles P. Russell, John G. Frazer, and Gustavus Langmann.

He announced also the following standing committees for the year.

STANDING COMMITTEES.

Committee on Library. — Drs. Thomas S. Bahan (Chairman), Geo. M. Beard, R. J. O'Sullivan.

Committee on Intelligence. — Drs. B. S. Thompson (Chairman), Wm. T. White, Jerome C. Smith, Robert Newman, James B. Hunter, Benj. F. Dawson, Andrew H. Smith, Salvatore Caro, Norton Folsom, Chas. S. Wood, F. A. Castle.

Committee on Meteorology.—Drs. David H. Goodwillie (Chairman), John Messenger, Fred. E. Hutchinson, Edward C. Harwood.

Committee on Diseases.—Drs. Moreau Morris (Chairman), A. B. Judson, Horace T. Hanks, Leonard Weber, Henry G. Piffard, Edward Bradley, T. Munson Coan, Samuel A. Raborg.

Committee on Finance. — Drs. Wm. B. Bibbins (Chairman), Thos. Addis Emmet, Edwards Hall, Joseph Kammerer.

A communication preferring charges against a member was received and referred to the Comitia Minora.

BLEPHAROPLASTY.

Dr. Knapp presented a patient upon whom he had restored the lower eyelid, with substantially the following remarks:

This woman suffered from epithelial cancer of the left lower lid, which I removed about six months ago. The disease was nodular in character. It extended, laterally, from the punctum to the outer canthus, and downwards considerably below the tarsal cartilage, involving the whole thickness of the lid.

I made the incisions for the removal of the growth as you see in this diagram—two incisions passing vertically downwards from the punctum and from the outer canthus to the extent of eight or nine lines, and being joined at their extremities by a horizontal one. I kept at a distance of at least a line and a half from the globe at every point, so as to be sure to get all the germs, going through the whole thickness of the lid—skin, orbicular muscle, cartilage, and conjunctiva. This left exposed a square surface, the eyeball being laid bare and some little space below it.

To fill up this gap I resorted to a somewhat peculiar method, which I had before employed in several cases. The horizontal incision, from the point where it joined the outer vertical one, was extended outwards (and very slightly downwards) across the cheek for a distance of nearly two inches. From the outer canthus a similar incision (directed very slightly upwards) was carried to the same extent. On the inner side the horizontal incision was extended about to the middle line of the nose; and from the punctum, for a short distance inwards, a careful dissection was so made around the canaliculus as to allow this to be stretched, along with the flap containing it. Both flaps were very freely dissected up, and then stretched so as to bring their vertical ends together at the middle of the lid, where they were fastened by interrupted sutures. They united perfectly, so that you can now hardly discover the line of union. A mucous lining for the new lid was made of conjunctiva drawn from the inferior fold.

This method has the advantage that it gives a lid perfectly adapted to the globe. The slight traction of the flaps, as they shrink a little, is lateral, not downward, and brings them close to the eyeball. There is no ectropion, and no unsightly swelling out of the flaps, such as are so often sources of inconvenience and disfigurement after other operations. Celsus says that when the whole lid is destroyed it cannot be restored. This is certainly true for the upper lid; for that has a large cartilage and a special muscle of its own, without which it could not perform its office. But the lower lid is comparatively inert. If fitted nicely to the globe, it will fulfil its triple function—of protecting the eyeball, holding it in place so as to allow of the ball-and-socket motion, and retaining the tears—without a cartilage and without a particle of muscular fibre. (It is possible, however, to bring in orbicular fibres from the sides.) You see that here there is not the slightest lachrymation; yet there is no deficiency of tears on the lower part of the globe, although so large a part of the mucous membrane was taken away. The eye is properly lubricated, and follows all the movements of its fellow with perfect ease. And the lids can be as easily and completely closed as on the other side, though the whole cartilage is gone and nothing of the old lid remains beyond the punctum. In short, the new lid answers every functional demand; there is barely a trace of the pseudoplasm; and except for the absence of lashes, you would hardly notice any difference between the two eyes.

A more customary operation is that of transplanting a flap from the temple. So far as I have observed its results, both in my own cases and in those of others, there has invariably been swelling of the flap, and more or less disfigurement. Another operation is that of removing the morbid growth by a V-incision, and filling up the triangular space by *glissement*, that is, by dissecting up the flaps at its edges and bringing them together. This, as it affords no lateral support, almost always draws the lid downwards, producing ectropion, and of course an overflow of tears.

The method which I have here shown has its limits. The stretching of a flap is always a calamity, and can be practised without risk of failure only where the skin is very supple. The integument of the lower eyelid, however, and of the parts adjacent, is supple enough to bear stretching as much as I have done in this case. I do not know how much more it would bear.

Dr. L. Weber remarked upon the wonderful accuracy with which the lid fitted the eyeball, such as could only have been attained by the traction of the lateral flaps.

Dr. Sayre had never seen a result approaching this. He wished to inquire whether the stretching of the canaliculus might not tend to close it and obstruct the passage of tears.

Dr. Knapp replied that, even if the punctum and canaliculus of the lower lid were obliterated, those of the upper would probably prove sufficient to carry off all the tears. But in this case, although the lower punctum was drawn outwards a line, or a line and a half, it seemed to perform its office completely.

The President stated that at the meeting of December 5th a paper would be read by Dr. Fordyce Barker. The Society then adjourned.

ARMY AND NAVY NEWS.

List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from November 4th, 1870, to November 17th, 1870, inclusive.

WIRTZ, H. R., Surgeon.—By S. O. 25, Headquarters Department of Arizona, October 13th, 1870: to proceed to Drum Barracks, California, and await further orders from these Headquarters.

WEBSTER, WARREN, Surgeon.—By S. O. 218, Headquarters Department of the East, November 4th, 1870: to proceed without delay to Fort Warren, Mass., and relieve Assistant-Surgeon J. H. Kinsman from duty as Post-Surgeon.

HAPPERSETT, J. C. G., Assistant-Surgeon.—By S. O. 231, Headquarters Department of the East, November 16th, 1870: the leave of absence—granted Assistant-Surgeon Happersett, in S. O. 123, Headquarters, Fort Washington, Md.—is extended 20 days on Surgeon's Certificate of Disability.

WHITEHEAD, W. E., Assistant-Surgeon.—By S. O. 218, Headquarters Department of the East, November 4th, 1870: relieved from duty at Fort Columbus, N. Y. H., and to proceed at once to David's Island, N. Y. H., and report to the Commanding Officer of that Post for duty.

COUES, ELLIOTT, Assistant-Surgeon.—By S. O. 218, Headquarters Department of the East, November 4th, 1870: upon being relieved at Fort Macon, N. C., to proceed to Fort McHenry, Md., and report to the Commanding Officer and to the Post-Surgeon.

KINSMAN, J. H., Assistant-Surgeon.—By S. O. 218, Headquarters Department of the East, November 4th, 1870: upon being relieved as Post-Surgeon, by Surgeon Warren Webster, at Fort Warren, Mass., to proceed to comply with par. 2, S. O. 176, c. s., from these Headquarters.

KINSMAN, J. H., Assistant-Surgeon.—By S. O. 227, Headquarters Department of the East, November 12th, 1870: granted permission to delay, for twenty days, proceeding to Fort Johnson, N. C., when relieved by Surgeon Warren Webster.

CALDWELL, D. G., Assistant-Surgeon.—By S. O. 241, Headquarters Department of the South, November 5th, 1870: having reported at these Headquarters, in compliance with S. O. 111, Headquarters of the Army, A. G. O., c. s., to report without delay to the Commanding officer, Post of Chattanooga, Tenn., for duty as Post-Surgeon, relieving Acting Assistant-Surgeon J. H. Van Deman.

BENTLEY, EDWIN, Assistant-Surgeon.—By S. O. 171, Headquarters Department of California, November 2, 1870: granted leave of absence for 30 days, with permission to apply for an extension of 30 days.

BARTHOLF, J. H., Assistant-Surgeon.—By S. O. 244, paragraph 1, Headquarters Department of the South, November 9th, 1870: to proceed without delay to Lebanon, Ky., and report to the Commanding Officer of that Post for temporary duty as Post-Surgeon, relieving Acting Assistant-Surgeon W. H. Hopper, U. S. Army.

PRUSSIAN LOSSES.—Lieutenant Von Langenbeck, a son of the eminent surgeon of Berlin, has died of wounds received in battle on the 18th of August. The only son and the son-in-law of General Staff-Surgeon von Grimm were both killed before Metz on the 18th. The sons of Dr. Simon of Berlin, Dr. Stilling of Cassel, and of several other medical men, have been wounded: the son of Dr. Lauer, Physician in Ordinary to the King of Prussia, severely.

New Instruments.

DURHAM'S NEW FORM OF TRACHEAL CANULA.

NOTES BY CHRISTOPHER JOHNSTON, M.D.,
PROFESSOR OF SURGERY, UNIVERSITY OF MARYLAND, BALTIMORE.

IN the year 1869, April number of the *Practitioner*, is to be found a very able article by Arthur E. Durham, F.R.C.S., "On some of the Difficulties and Dangers of Tracheotomy, and the best means of obviating them." Among the dangers enumerated are those arising from the pressure and irritation of the canula, and which are claimed to be dependent, in great measure, upon faults and defects inherent in the tubes First, the curve of the ordinary English canula, of the French canula, and of Dr. Fuller's bivalve canula, is objectionable, because "most frequently the anterior wall of the trachea is found, in post-mortem examinations, to be ulcerated exactly at the spot upon which the extremity of the tube often impinges."

Secondly, "All these different forms of tracheal canula are open to the objection that they are rigid throughout."

"But the improved French canula, designed by M. Roger, is so contrived," continues Mr. Durham, "as to obviate, more or less effectually, this source of danger; and its principle is adopted in the construction of the canula which will presently be described.

"Thirdly, apart from their liability to cause ulceration, the canulas in ordinary use have various faults and deficiencies which may give rise to much trouble. Sometimes the tube is too long, in which case it presses against the posterior wall of the trachea, and is often ejected. Sometimes it is too short, and cannot be retained unless the plate be deeply buried in the wound.

"Fourthly, ordinary, and even improved tubes are difficult of introduction, in not being provided with a *pilot*." It is not, however, contended that the pilot is an original device, for such an aid, in some form or other, has long been familiar to the profession.

Besides the foregoing, we may add the dragging forward of the trachea by all canulas having a single and circular curve.

To obviate these deficiencies, a new form of canula is proposed by Mr. Durham, which we know, from experience, to be greatly superior to "any hitherto made known." The chief points of originality, says the author, are in the shape of the canula, and the arrangement by which it is capable of being readily adjusted to the depth at which the trachea may be found to lie.

"The instrument consists of an outer tube, which is intended to pass *straight* back into the trachea, and then to turn downwards in such a way that its extremity shall occupy the middle of the trachea, and its edges shall not unduly press against the mucous membrane. The straight portion of the tube slides backwards and forwards in a collar, but can be fixed at any point by means of a screw. The portion of the tube in the wound may thus be regulated in length according to the depth at which the trachea is situated. The projection of the outer end of the tube beyond the collar is by no means disadvantageous. It renders expelled mucus, etc., less likely to be drawn in again by the next inspiration.

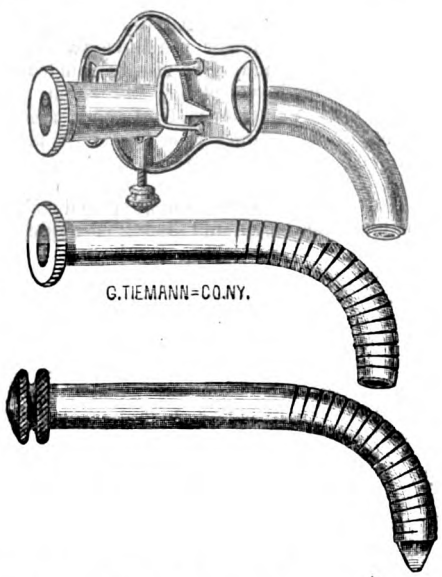
"The collar is attached to a small plate, which is connected with the neck-plate by means of two alar processes passing under little wire arches (upon the prin-

ciple of Roger) in such a manner as to permit a certain amount of motion in various directions. The tube is thus enabled to accommodate itself during various movements and changes in relative position of the trachea and superficial parts of the neck.

"The inner tube is peculiar in that its distal portion consists of several small pieces joined together, somewhat in 'lobster-tail' fashion. The adoption of this plan of construction is necessary to enable the tube to pass along the straight portion of the outer tube, and then to curve down and fit into the perpendicular portion. This inner tube is so long as to project somewhat beyond the extremity of the outer tube—a very essential point.

"Lastly, the blunt-pointed pilot trocar, made also in 'lobster-tail fashion,' and mounted in a handle for security of manipulation. This accessory certainly deserves to be universally adopted."

The article in question led us to order from London last summer two sizes of Durham's canula, with pilot; and being satisfied with the practical operation of the instrument, we referred its reproduction in this country to Messrs. George Tiemann and Co., who not only undertook the manufacture on our recommendation, but also made two changes, which are to be regarded as real improvements. Besides the alterations presently to be noted, the cost of the American canula is less than half of twenty-five dollars, which we paid for the English one.



The first modification consists in transferring the long collar screw from the side to the sternal edge, and curtailing its length.

The second improvement affects the inner tube and the pilot. Instead of the "lobster-tail" arrangement for flexibility, a spiral is substituted, which occupies less space, is easily cleaned, and lessens the price. We may also add that we have found the spiral to remain *in situ* by its "spring" when the loose "lobster-tail" became disengaged.

As to size, we cannot do better than refer to Mr. Holmes's well-known volume on "The Surgical Treatment of Children's Diseases." On page 324 he says: "An idea prevails that the trachea tubes in common use are too small." Now, apart from the difficulty of introducing a large tube in a small child, "what necessity can be imagined to exist for a larger opening than nature gives us? The aperture of the glottis is not larger, I think, on an average, than that of the trachea tubes in ordinary use."

On page 325 the same author gives the following summary of Mr. Marsh's measurements of the trachea and cricoid at various ages, the latter because "the windpipe at the cricoid cartilage is the smallest part of the air-tube."

Age.	Trachea.	Cricoid.	Age.	Trachea.	Cricoid.
1	10	9	6	13	11
2	10½	8	7	13	12
3	11	9	12	20	14
4	13	9	16	20½	18½
5	13½	11	Adults.	26	23½

The measurements are in $\frac{1}{10}$ths of an inch.

Again, on page 326, Mr. Holmes continues: "I have measured three of the tubes in actual use at the Children's Hospital. The smallest (which I have myself introduced above the thyroid isthmus at a little over a year old) is of the diameter of $\frac{4}{10}$ths of an inch. This is the just extent of the long diameter of the elliptical opening of the glottis at the age of two years eight months; so that the whole area of the section of the tube would be much larger than the glottis was found to be at double the age. The second tube measured $\frac{4}{10}$ths of an inch, exceeding considerably the size of the glottis at three years ten months; and the third, $\frac{5}{10}$ths of an inch: much larger than the glottis at the extreme limit of ten years, at which we admit in-patients. As far, therefore, as the tubes in ordinary use in childhood are concerned, I believe that they are usually larger than the glottis, and therefore as large as can be required."

In conclusion I may state that I am still most favorably impressed with the superiority of the Durham canulas and pilot over any other forms. They are introduced with the utmost facility; and I find, by reference to my note-book, the canula is perfectly adapted to the inclination of the trachea, and adaptable to its varying depth, and its point will not fret the anterior wall of the trachea.

I have just removed an English Durham tube from the neck of a child aged 5 years, on whom I did tracheotomy, and I am convinced that the excellence of the instrument contributed largely to the attainment of a favorable termination of the case.

I may be allowed to add that besides the English canulas I am provided with a set of Tiemann's improved. In all of them the only thing to be desired is the possibility of establishing an aperture at the angle of *both* inner and outer tubes. I now use the outer one, so perforated, alone, from time to time, under surveillance, but replace the inner one at intervals, lest inspissated mucus might obstruct the outer canula. I am also in the habit of testing the condition of the air passages by inserting a wooden plug into the mouth of the outer tube, and maintaining it there for a while.

28 Franklin street, Baltimore, *October* 13, 1870.

Prof. E. R. Peaslee will deliver four lectures on Ovariotomy at the College of Physicians and Surgeons, during November, on Friday afternoons at 4 o'clock. These lectures are *free*, and the Profession are particularly invited.

Fighting Neutrals.—The *Revue de Thérapeutique Médico-Chirurgicale* of September 15th states that at the battle of Sédan five hundred surgeons and hospital nurses took part in the fight, and left more than two hundred of their number dead on the field of honor.

Medical Items and News.

NEW YORK PHYSICIANS' MUTUAL AID ASSOCIATION.—At a large meeting of this Association, held at the Mott Memorial Library, on Nov. 10th, the following officers were elected for 1870-71: James Anderson, M.D., *President;* Wm. W. Reese, M.D., of Brooklyn, *1st Vice-President;* C. R. Agnew, M.D., *2d Vice-President;* J. S. Monell, M.D., *Recording Secretary;* S. Ayers, M.D., *Asst. Secretary;* Horatio S. Smith, M.D., of Brooklyn, *Corresponding Secretary;* E. H. Janes, M.D., *Treasurer.*

Trustees for one year: Drs. Wm. N. Blakeman and Alfred Underhill, of N. Y.; C. S. Michel, of Brooklyn.

Trustees for two years: Drs. Gurdon Buck, R. J. O'Sullivan, and M. Herzog.

Trustees for three years: Drs. Joel Foster, James Kennedy, and J. H. Hinton.

From the reports of the Recording Secretary and Treasurer we learn that 5 members have died since the organization of the Association, and 162 members have been proposed and elected during the past year.

The Association, which includes Brooklyn, is now in good working order, numbering several hundred members, and has some excellent features incorporated in the new Constitution, such as: In case a member is destitute, having no family, he can draw on his assessment; also the Association has been granted the privilege of a bed and room, with the attendance and comforts of each of the hospitals in New York and Brooklyn, in case of extreme need, etc.

The managers anticipate this year a sufficient number of members to swell the donation to the heirs to two thousand dollars, upon the death of each member.

CONTAGIOUS DISEASES.—Dr. Moreau Morris presents the following statement of the number of contagious diseases, as reported to this Bureau during the week ending Nov. 5th inst., in comparison with the previous week:—

Week Ending	Typhus Fever.	Typhoid Fever.	Relapsing Fever.	Small Pox.	Scarlatina.	Measles.	Diphtheria.
Oct. 29.	4	26	20	1	20	10	9
Nov. 5.	4	22	18	3	39	18	10

MEDICINE IN INDIA.—At a special meeting of the Hunterian Society, in London, Dr. Baboo Chunder Roy gave the subjoined account of medicine in India, which we take from the *British Medical Journal:* The physicians of India had sprung from two of the castes—the Brahmins, who were the most highly educated and from whom the priests were chosen, and the Boyshos or traders, who were not allowed to learn Sanskrit or to reach the higher education of the Brahmins. Medicine and surgery were distinct; the latter being entrusted to barbers, whose operative skill was very limited. Medicine was from very ancient times divided into anatomy, materia medica, and the treatment of diseases. The study of anatomy was very imperfect, in consequence of the prejudice against handling dead bodies. What knowledge of anatomy the Hindoo possessed, was gained from the dissection of goats; and an acquaintance with the human skeleton was obtained by allowing bodies to remain in water till the bones and ligaments alone were left. The umbilicus was supposed to be the centre of the vascular system. The blood was regarded as a mixture of humors. The materia medica attracted attention at an early period; and the articles were described with a view to their dietetic as well as to their therapeutic properties. Mercury, arsenic, iron, and several other mineral remedies were known in Hindoo medicine many centuries ago. Gold dust entered very extensively into the formulæ; perhaps not so much for the sake of increasing the therapeutic value of the medicines as their cost. Sesquioxide of iron was the chief basis of tonic remedies. Arsenic had been long used in the treatment of intermittent fever. There were a large number of remedies belonging to the vegetable kingdom in use in India from remote ages, some of which, as bael, chirayta, etc., had been received into the *British Pharmacopœia.* Baboo Chunder Roy recommended a careful investigation of Indian medicinal plants; believing it probable that among them would be found some valuable remedies for the prevalent diseases of the country. In the works on practice of medicine, the description of symptoms was very exact, but the treatment was empirical. In fevers, low diet was enjoined; the patient was kept for forty-eight hours without medicine; then bitters and purgatives were administered; and then, if the fever persisted, arsenic in divided doses. This treatment rarely failed to arrest the disease in ten days; but it left the patient's constitution in an impaired state. Surgery was in old times entrusted to barbers, whose practice was limited mostly to the treatment of ulcers, abscesses, etc. But for ages there had been persons who performed the operation for depression of cataract, cupping (by means of cow's horns), bleeding (in the calves of the legs), etc. Hygiene had long held a place in the Hindoo system, being mixed up with religious rites. Washing in the Ganges was thus made a religious ceremony. The flesh of the ox was forbidden, on account of the use of the animal in agriculture, and of the cow in yielding milk; and that of the pig on account of the filthy habits of the animal. Dry earth had been long used for removing offensive smells. Change of climate, in the form of pilgrimages to distant lands, had long been a remedy in chronic diseases. With all this, there was ignorance of some of the fundamental principles of hygiene. Poison and pure air were in the same category; and a Hindoo sick room was rigidly closed at all points.

IOWA STATE UNIVERSITY.—From the Catalogue of the Iowa State University for 1869-70, we learn that 434 students are in attendance in the several departments of this young and thriving institution. The medical department of the University has been organized at Iowa City, a place of 12,000 inhabitants, and fifty-five miles west of the Mississippi river. The fees are merely nominal ($20).

DEATH OF OLD PERSONS.—John Van Emburgh, of Kearny, N. J., died on Thursday, the 22d of September, aged 104 years. At the age of 96 he married a German girl sixteen years old, and within a year she presented him with twins.

John Kitts, the oldest inhabitant in Baltimore, Md., died September 25th, aged 108 years. He was an army teamster during the Revolution.

HARVARD MEDICAL COLLEGE.—Prof. W. T. Lusk, of Long Island Medical College, will deliver a course of lectures on Physiology, at Harvard Medical College, the ensuing winter.

A NEW WORK BY DARWIN.—This distinguished author has a new work in press to be out this season. It is entitled the "Descent of Man and the Selection in Relation to Sex."

GASTRIC ULCER.—Ulcer of the stomach is quite common in some parts of the Continent of Europe and in England; but it is comparatively rare in this country.

PHOTOGRAPHY OF THE SUN.—Prof. Young, of Dartmouth College, has succeeded in photographing one of the protuberances on the sun, a scientific feat often before attempted, but never accomplished. The operation was performed with a telescope, assisted by a spectroscope.

GERMAN PSYCHOLOGY.—The *Archiv für Psychiatrie und Nervenkrankheiten*, established by the late eminent Prof. Griesinger, is now ably conducted by Dr. L. Meyer and Dr. C. Westphal, two learned German psychologists.

A MEDICAL TRANSLATOR.—A new translation of the "Satires of Horace," by Dr. Andrew Wood, an eminent Scotch physician, is announced in Edinburgh.

THE CAUCASIAN AND AFRICAN RACE.—Harvey L. Byrd, M.D., Prof. of Obstetrics in Washington University of Baltimore (*Balt. Med. Journ.*), asserts that the negro requires more carbon for the well-being of his organism, and far less oxygen, at least during sleep, than the white man.

FRENCH PRIZES CONFERRED.—M. Le Roux received this year the *Annual Tremont Prize*, worth 1,100 francs, for his researches on thermo-electric currents.

The Poncelot Prize was bestowed on Dr. J. R. Mayer, at Heilbronn, for his work on "The Mechanical Theory of Heat."

Medals, of the value of 3,000 and 2,000 francs each, were given to MM. Legros and M. Onimus and M. Cyon, for their researches on the application of electricity to therapeutics.

Dr. Friedel received the *Jecker Prize* for investigations on organic silicium compounds.

PROFESSOR MAGNUS' SUCCESSOR.—Prof. Helmholtz, late of Heidelberg University, has accepted the chair of Physics in Berlin University, made vacant by the death of Prof. Magnus.

A SMALL SALARY TO A NOTED LECTURER.—Prof. Huxley, who will soon visit our country, receives only £600 per annum, from the British Government, for his scientific lectures given in the School of Mines.

PETROLEUM IN VERA CRUZ.—Twelve petroleum wells have lately been discovered in the district of Minutitlan, State of Vera Cruz.

HAIR DYES AND LUNACY.—A French journal asserts that 7 per cent. of lunatics are made so by the employment of hair dyes.

FRENCH CATHETER GAUGE.—A prominent writer in the *Dublin Quarterly Journal of Medical Science*—Dr. B. Kills Richardson — confirms all that Sir Henry Thompson advocates in favor of the French catheter gauge over the English one. Were it not for the fine French bougies (the ½ and ¾), as well as the larger half-sizes, his initiatory dilatation of several very close strictures would have been unnecessarily prolonged.

Such eminent manufacturers as the Messrs. Weiss, of London, are now making all their instruments on the French scale.

SMALL-POX AMONGST THE FRENCH SOLDIERS.—Small-pox, which has been so common in France, and especially in Paris, is prevalent also in the French army. Five of the wounded French now in the hospitals of Berlin were taken ill with it and were brought to the small-pox wards of the Charité Hospital; two of them died. The invasion of France by the German armies will be a test, on the largest scale, of the efficiency of the vaccination and revaccination performed on every recruit of the Prussian army.—*British Med. Journal.*

HAIR DYE.—J. B. A. Risk, M.D., Morgan, Ky. (*The Cin. Med. Repertory*), submits the following innocuous hair dye: A substance for a safe and effective hair dye can be found in the black walnut. This can be obtained by macerating the green hulls in water; the coloring principle is taken up, and this is imparted to the hair by application; but it should be applied carefully, as it will stain the skin also.

After the hair is thus colored, the subjoined mixture applied for a few nights will improve its appearance very much: Mix equal parts of water and glycerine, and to each pint of the mixture add lac sulphur, 3 ij, and a few drops of oil of bergamot. Before this compound is applied it should have a severe shaking, so as to mix the sulphur with the fluid. Apply once or twice a week at night.

ACUTE GASTRIC SOFTENING.—Jaeger, Cruveilhier, and Billard describe this form of gastritis which occurs in very young children, and leads to softening of the mucous lining of the stomach. They have each made this softening a subject of special study; yet its nature is not fully understood. Cruveilhier has seen it occur in epidemics.

CANCER.—Cancer is found more frequently in the stomach than in any other organ excepting the uterus. Of 9,118 cases of cancer which occurred in Paris from 1837 to 1840, 2,303 were in the stomach.

A DIAGNOSTIC SIGN IN ACUTE ENTERITIS.—Dr. Stokes, of Dublin (*Cyclop. of Prac. Med.*), first noticed the following sign characteristic of this disease: Toward the right of the umbilicus, it is not uncommon to find a marked pulsation, as if from throbbing of the abdominal aorta or of its large branches.

PHOSPHORIC ACID IN THE URINE.—The average quantity of this acid passed by an adult male in twenty-four hours is, according to Vogel, nearly fifty-three grains.

TEMPERATURE OF THE BODY.—In temperate climes, according to Wunderlich, the average heat of the body is estimated at 37° centigrade in the axilla; that of freshly voided urine is about the same. Expressed in the scale used in this country, it may be stated that the average heat of sheltered and internal parts of the body is 98.6° Fahr.

PHYSICAL SIGN IN BRONCHIAL DILATATION.—Skoda (*Allgem. Wien. Mediz. Zeitung*) describes, as a peculiar physical sign present in sacculated bronchial dilatation, connected with disease of the lungs, a large and coarse crackling, called by him the large bubbling, dry crepitant râle.

PHYSICAL DEGENERACY.—According to Dr. Nathan Allen, of Lowell, Mass. (*Journ. Psychological Medicine*), there are at the present time many less children for the same number of families than formerly. By the census returns of 1765 and 1865, there are now found only about one-half as many children, under 15 years of age, relatively to the adult population, as there were one hundred years ago.

Formerly the average number of children to each family would range from 6 to 8, but probably now will not exceed 4, and may not be much over 3. It is a fact, settled by mortuary statistics, that about two-fifths of all children born die before reaching adult life.

THE INVENTOR OF SPECTACLES.—On a tombstone at Florence is this inscription: "Here lies Salvino Armato d'Armati, of Florence, the inventor of spectacles. May God pardon his sins. The year 1318."

Original Lectures.

THE PATHOLOGY OF TUBERCULOSIS.

BEING REMARKS MADE IN THE DISCUSSION OF THE SUBJECT BEFORE THE NEW YORK ACADEMY OF MEDICINE.

I. By William H. Draper, M.D.,
II. By John C. Peters, M.D.,

STATED MEETING NOV. 3, 1870, DR. H. D. BULKLEY, IN THE CHAIR.

I. Remarks by William H. Draper, M.D.

It is with some diffidence that I appear to open the discussion upon the questions involved in the papers which have been read at the two last meetings of the Academy. Dr. Flint, in the very able and interesting paper which he read at the last meeting, reviewed the recent opinions upon the pathology of phthisis, and brought to the task the calm and conservative judgment which is only attained by a rich experience and ripe culture; and if in the remarks I am about to make I shall take occasion to differ with him, I would have you bear in mind that I am only expressing the opinions of those whose observations and experience entitle them to equal attention and respect.

In the paper which I had the honor to read a month ago, I attempted to lay before you an historical review of the pathological views which have been held since the beginning of the present century in regard to pulmonary phthisis. Beginning with the opinions of Bayle and Laennec, I endeavored to trace the origin and progress of the opposing theories which have divided the profession upon this subject up to the present time; and one of the results of our inquiry was the development of the fact, that in many essential points the opposing opinions to-day are but a reflection of those which divided Laennec and Broussais. We deemed this an important fact in the study of this question, because the new views, as they are called, are not, strictly speaking, new. They are, in truth, in many particulars, as old as the views to which they are opposed. They are new, in the sense they have received new life from the latest discoveries in pathology, and therefore they appeal the more strongly to our consideration at the present day.

It is evident that Dr. Flint, while he is disposed to admit that recent investigations tend to modify the old views of the pathology of phthisis, still inclines to hold fast to the doctrines of Laennec as to the specificness of tubercle, and to oppose the inflammatory origin of consumption and the secondary nature of tuberculosis. We do not propose to repeat the evidence given in our first paper, which seems to us incontestable, that Laennec confounded diverse products under the name of tubercle. It is sufficient for our present purpose to renew the statement, for which we think sufficient proof exists, that the very fact that tubercle has an anatomical character and site of its own, distinguishing it from caseous substance, which has equally distinctive anatomical elements and location, shows that these two products are the result of different morbid conditions. We shall confine ourselves this evening to a few remarks on certain practical points suggested by Dr. Flint's paper.

The first point to which we wish to call attention is the etiological relation of bronchial catarrh to pulmonary phthisis; for this question is the most important, perhaps, in a practical point of view, of all the questions embraced in the discussion. It involves directly the inflammatory origin of a large number of cases of pulmonary phthisis, and indirectly involves the question as to the consecutive nature of true tuberculosis, reserving this latter term to designate the cases in which the evidences of inflammation are complicated with miliary granulations.

Laennec admits that "it is certain that in the majority of phthisical persons the first symptoms of the malady are those of a pulmonary catarrh, but that it is equally certain that very voluminous and numerous tubercles are found in persons who have really no sign of catarrh." Laennec reasons from this latter circumstance that the catarrh, when it appears to be the commencement of a consumption, is really a secondary pneumonia, preceded by the deposition of tubercle; and he uses as an argument against the theory that the catarrh is the primary affection, that "thousands of persons have bronchial catarrhs several times a year, and very few become phthisical; and, moreover, that many have a mucous or pituitous catarrh, with abundant expectoration, and advanced age, without becoming phthisical." We might, it seems to us, with equal propriety, argue that there was no connection between stricture of the urethra and gonorrhœa, because the great majority of those who suffer from urethritis do not have stricture as a consequence. Another argument which Laennec uses in favor of the non-catarrhal origin of pulmonary phthisis would hardly be accepted by clinical observers of consumption in this country, viz.: "That the maritime population of our coasts is much more subject to pulmonary catarrh than the inhabitants of the interior, and that the latter are much more subject to pulmonary phthisis than the former." We believe that the statistics in this country would not confirm this statement, but would rather prove that consumption is most frequent where catarrh is most common, viz., our coasts, where the climate is characterized by the most sudden and extreme changes of temperature, and by excessive moisture.

Laennec, in discussing the relations of phthisis to catarrh from the anatomical point of view, declares that in order to prove that pulmonary phthisis is even a sequence of catarrh, it must be shown, scalpel in hand, that the one passes into the other, and that this is impossible, because the catarrh is an inflammation of the bronchial mucous membrane, while the tubercles are accidental productions, veritable foreign bodies developed in the pulmonary substance, and which may also be found in all the other tissues of the body, and which are very rarely found in the substance of the bronchial mucous membrane.

This argument, in the light of the modern pathology of tubercle, falls to the ground. Laennec maintained that caseous masses and granulations were only different forms of the same morbid products. Microscopic anatomy has demonstrated that they are distinct substances, that is to say—that caseous masses are frequently of inflammatory origin, and, when alveolar in their site, probably always so—while the granulations, the true tubercles, which are found in the connective tissue surrounding the blood-vessels, constitute a genuine neoplasm. To maintain the doctrines of Laennec in regard to pulmonary phthisis, therefore, is to ignore all progress in pathological anatomy. It is not, as has been suggested, a mere dispute about terms, but about things. If we admit that the microscope has demonstrated that the true tubercle granulation is one thing, and that caseous masses are another; that granulation is composed of cells of definite shape and size, and developed in a particular tissue, and that caseous masses

are composed of cellular bodies of entirely different character, and developed in a different locality, then we must admit that the diseases in which these products occur are essentially different diseases, whatever difficulties we may encounter in distinguishing them clinically. Every one who has had any experience in the post-mortem examination of cases of phthisis has observed cases in which the so-called caseous masses and excavations have existed without a trace of tubercular granulations. Laennec himself describes such cases in his account of what he terms the gray tuberculous infiltration. He says "this infiltration is formed frequently around tuberculous excavations: one sees it also developing itself primitively in lungs which do not yet contain tubercles, but this is extremely rare. Sometimes, however, tuberculous masses of large size are formed in consequence of a similar impregnation or infiltration of tuberculous matter in the first or semi-transparent degree, and without previous development of miliary tubercles." We have quoted this statement from Laennec to show two things: first, that even he did not regard the miliary granulation as an essential element in the pathology of phthisis; and secondly, to note the fact that he speaks of the granulations as not *yet* formed where infiltration had already occurred,—as if he regarded the tuberculous granulation as sometimes a sequence of the infiltrations in point of time. And here it is worthy of remark, that no one can read at the present day Laennec's incomparable and exhaustive descriptions of the lesions of pulmonary phthisis without paying homage to his truthful accuracy of observation as a pathologist, no less than to his genius as the discoverer of auscultation. It is not surprising that the impress of his teaching should still be manifest, nor strange that it should have required a genius of equal magnitude to efface it. The glory of Laennec is imperishable, and the work he accomplished for pathology only paved the way for the brilliant discoveries, in our day, of his compeer beyond the Rhine.

The second point to which we wish briefly to refer, is the present theory as to the specificity of tubercle. Dr. Flint, in his paper, alludes to the experiments of Villemin as demonstrating the specificity of tubercle—that is to say, as showing that tubercle is reproduced only by the inoculation of tuberculous matter in its granular or caseous form. But we desire, in the first place, to call attention to the fact that Villemin accepted Laennec's views of the identity of tuberculous granulations and the caseous or infiltrated tubercle; and, in the second place, to refer to the complete refutation of Villemin's conclusions furnished by the subsequent experiments of Andrew Clark, Wilson Fox, and Waldenburg. Villemin did indeed reproduce tubercles by the inoculation of tuberculous granulations and yellow tubercles, but, as is well known, precisely similar effects followed the inoculation of a great variety of morbid products, and even of such foreign substances as purely divided aniline blue and carmine, in the experiments of Clark, Fox, and Waldenburg.

These experiments seem to prove conclusively, that tubercle lacks the essential element of specificity, in the sense in which this term is applied to the virus of variola, syphilis, and other diseases which are only reproduced by their own infectious principles. Villemin's objections to the results of the experiments to which we have just alluded are, we think, scarcely tenable. He says that when tubercles were produced by the inoculation of other substances than granular or caseous tubercle, either the observers were mistaken in supposing that the products which resulted were tubercles, or that they unconsciously introduced tuberculous matter with other substances. The first supposition, that the products of the inoculation were not tuberculous granulations, is an assumption unworthy of consideration; and the second, that tubercle virus was latent in the other substances with which inoculations were made, is certainly improbable. And even supposing that the virus did lurk in the morbid products that were used, how would the results of the inoculations with purely divided inorganic substances be explained? But do these later experiments prove anything more than that tubercle is *not*, in the strict sense of the term, a specific product? Are the tuberculous granulations secondary to the caseous masses? In answering this question, it must be confessed that we leave the field of absolute demonstration, and enter into the region of speculation; and yet we believe that the theory which has been advanced upon this point is justified in no slight degree by pathological and clinical evidence.

We considered at some length, in our first paper, the pathological evidence presented by Buhl, Hoffman, Niemeyer, and Waldenburg, in favor of the theory as formulated by Waldenburg—that "miliary tuberculosis is a resorptive disease, produced by the absorption of very minutely divided corpuscular particles into the vascular circulation, and their deposit in the form of granulations at numerous points in various organs." It will be remembered that in the inoculation of animals the substance which most frequently produced tuberculosis was caseous matter, whether resulting from true tubercles, or from inspissated pus, or from hyperplasia of lymphatic glands—hence the conclusion "that the existence of caseous matter in any organ of the human body is the most important and most frequent cause of tuberculosis."

The frequency of these caseous masses in the lungs, as the sequence of lobular pneumonia, has led to the suspicion that the absorption of the detritus of these masses is the most common cause of tuberculosis of the lungs. And the fact, which was noticed and most accurately described by Laennec, that the tuberculous granulations were formed about the periphery of these masses and excavations, serves to support this idea of a local infection. The occurrence of the granulations upon the pleura, near to underlying cavities, or caseous masses, and their existence also on the peritonæum, in the immediate neighborhood of ulcerating intestinal glands, is further evidence of their secondary character. Buhl, Hoffman, and others, have accumulated from careful post-mortem inspection much proof of this kind, to show that the development of tuberculous granulations is the result of local infection, and that, when the process becomes generalized, the fact is to be explained through a multiplication of the foci by infection.

Waldenburg quotes Rokitansky as authority for the statement that only in rare instances is acute tuberculosis a primary disease. It depends, he says, in most cases upon a preceding fibrous tuberculosis, especially of the lungs and lymphatic glands; and hence, as a rule, that the miliary tuberculosis is confined to the organ affected with the fibrous tuberculosis. It must be remembered that Rokitansky calls caseous products tubercle, and distinguishes the granulation by the term miliary. Virchow, too, expresses the confident opinion that, in the great majority of cases, the miliary tuberculosis is preceded by caseous bronchial or mesenteric glands, caseous nodules in the lungs, or isolated ulcers in the intestine, but he admits that in rare instances of miliary tuberculosis no infectious masses can be found. Authorities are nearly unanimous that the circumscribed tuberculosis in the meninges is almost always a secondary or connective disease. Buhl describes

nine cases, in every one of which primary or pre-existing caseous masses were found in the lungs or lymphatic glands.

Rokitansky also asserts that in the great majority of cases tubercular meningitis is a secondary affection—preceded by tuberculous disease in the lungs, lymphatic glands, or brain. It is also known to be preceded in some instances by suppurative discharges from the ear.

It is interesting in this connection to note an observation made by Waldenburg in regard to the causes of phthisis recognized by the ancients. It was believed formerly that phthisis occurred in consequence of the suppression of customary secretions, or excretions—whether physiological or pathological; as, for example, by the suppression of blennorrhœa, cutaneous eruptions, and the sudden healing of chronic ulcers and fistulæ; after sudden checking of menstruation, and hæmorrhoidal discharge and the like.

It is not impossible that science may yet confirm in this instance, as it has done in many others, the correctness of the deductions made by the ancients, from purely clinical evidence.

It may be objected to this evidence of the secondary nature of miliary tuberculosis that the exceptional cases, where no infecting masses can be found, prove that there is no necessary relation between caseous masses and miliary tubercles. All that can be said in answer to this objection is, that the infecting mass may have escaped detection; and, considering the fact that this relation has not until late years been suspected, it is not unreasonable to suppose that greater care in post-mortem examinations may show that the exceptions which have been noted were probably only apparent.

We leave here the anatomical considerations which tend to show the etiological relations of miliary tubercles to caseous masses, and pass to a brief review of the clinical evidence which may be brought to bear upon this subject.

It has been remarked that miliary tuberculosis, especially in its acute form, is oftentimes difficult to distinguish from typhoid fever. It presents the history in many instances, in a remarkable degree, of an acute infectious disease. And the cases are not rare where the first suspicion of tuberculosis has occurred at the post-mortem inspection. The miliary tubercles constitute, so to speak, a sort of eruption in the lungs and other organs, which may entirely escape detection. The symptoms are those of an infectious disease, and the only certain means of differentiating the disease in its earlier stages from typhoid fever is the evidence of previous disease in the lungs, or of caseous masses in the glands or other organs. That the origin of these cases lies within the individual, and that they are not specific in their origin, in the sense in which the exanthemic fevers are, is evident from the fact that such cases are never epidemic, and that they are not dependent upon telluric or atmospheric influences. The symptoms of blood-poisoning which we observe in this disease are explicable, as those of pyæmia are, by the absorption of corpuscular elements into the circulation. It is not only in general tuberculosis, however, that the similarity of tuberculous disease to essential fever is observed.

The difficulty in some cases of differentiating between infantile remittent and a localized tuberculous meningitis, has often been encountered. Again, in the history of pulmonary phthisis it is by no means uncommon to observe severe febrile symptoms, of recurrent form, suddenly developed, which cannot be accounted for by the occurrence of an intercurrent inflammation. These are the cases in which, as Niemeyer expresses it, the patients have suddenly become tuberculous—in his opinion, the greatest danger to which the majority of cases of pulmonary phthisis are subject.

We have endeavored to present a few of the more important points involved in the discussion of the pathology of pulmonary phthisis. They may be summed up as follows: 1st. The diversity of pathological processes presented in the pathology of pulmonary consumption, as shown by the microscopic anatomy of the different morbid products which are found in the lesions of this disease. 2d. The clinical evidence of the inflammatory origin of numerous cases of consumption, as indicated by their catarrhal origin. 3d. The non-specificness of true tubercle, as proved by the inoculation experiments. 4th. The hypothetical view of true tuberculosis as a resorptive disease, and as a sequence of caseous masses in various organs.

There are several other important questions connected with the discussion of this subject relative to the contagiousness of phthisis, its hereditary history and treatment, of great practical importance, which were considered by Dr. Flint, and which we trust will be made the topic of further remark by the members of the Academy whose knowledge and experience enable them to speak upon these questions.

II. Remarks by John C. Peters, M.D.

In accordance with the desire of the President that all the Fellows, or as many as possible, of the Academy, should prepare themselves for a discussion of the so-called new views of tuberculosis, I have made some preparation.

This was the more easy, as I had paid somewhat particular attention to the subject in 1854, and again in 1860—and more or less, perhaps less, since then.

I find nothing very new, if we admit all the facts and theories of Virchow and Niemeyer, and even add still more to them, derived from the labors of such excellent physiological chemists as Simon of Berlin, Lehman of Leipzig, and Day of St. Andrew's College, Edinburgh. They are simply a return to the notions of Carswell, that tuberculosis commences in the air-cells and smaller bronchi; and to those of Addison, Broussais, Wilks, etc., that it generally arises from some form of inflammation of a low type; and to those of Hasse, Preuss, Cerrutti, Vogel, Guterbock, etc., that tubercle is always caseous.

Even if we side with Virchow and Niemeyer, it is not yet necessary to modify seriously the doctrines of Laennec and Louis, or those of Swett, Clark, or Flint, or the opinions of the mass of the profession in this and every other country.

This arises principally from the fact, that our views of the nature and treatment of inflammation are very different from what they were in the times of Laennec and Broussais; and it may easily be made very clear that it would have been a great misfortune, from the times of Laennec almost down to the present day, if Laennec had adopted Broussais's, or even Niemeyer's notions of inflammation, provided he had carried them out to the full extent that Broussais had impressed upon them.

In our times, which are those of Niemeyer, it makes very little difference whether we lean to the theory of the subacute inflammatory, or dyscratic origin of tubercle. We treat all fevers and inflammations very differently now from what Broussais did of old, and the treatment of tuberculosis is not very seriously modified by Niemeyer, simply because he has adopted the modern or restorative treatment of inflammation.

It also makes very little difference whether we cling to the idea that there is only one form of tubercle, or admit that there are two. For true miliary tubercle often undergoes the caseous degeneration; and primary caseous deposits are often followed by the secondary formation of miliary tubercles, as is proven by the experience of every practical physician who is in the habit of seeing or making post-mortem examinations; and we believe that both the miliary and tuberous forms of tubercle are made up of casein.

Every observing physician must have seen cases of true general miliary tuberculosis occurring in almost every organ, viz.: in the membranes of the brain, in the lungs, pleura, spleen, peritonæum, kidneys, etc., and yet not preceded by any caseous or yellow tubercle that could be discovered.

Again, every physician must have seen cases of primary and chronic scrofulous or tuberculous disease of the glands of the neck, followed by miliary tubercles of the brain, lungs, etc., not attended by any caseous or yellow tuberous tubercle, or mass, in any internal organ that could be discovered. The two diseases precede or follow each other indiscriminately, because they are closely allied to each other, if not absolutely identical.

These remarks may seem all the more strange because I strongly incline to some of the so-called modern views of tuberculosis, except I think them very old.

To make these points more clear, Dr. Peters exhibited to the members of the Academy thirty-three colored plates of portions of lung, showing tuberculosis acuta vel miliaris; pneumonia catarrhalis of children; Niemeyer's catarrhal pneumonia; pneumonia ulcerosa; connective tissue corpuscles; cancer formed in connective tissue like pus, and tubercle; tubercle granules in air-cells from Bennett, 1858; tubercle from lung tissue, normal pus globules, tuberculous matter with melanosis, etc.,—all from Dr. Swett, 1852; bronchitis with both plastic and cheesy deposit, expectoration in hepatization, congestion, etc.,—from Dr. Dobell; blood globules in phthisis from Thompson; deposits of tubercle both inside and outside of the air-cells and bronchi, etc.

1st. As to the question whether there are one or two forms of tubercle.

The majority of the profession are now inclining to the opinion that there is but one elementary form of tuberculous deposit, viz.: the gray granulation, or miliary tubercle: and that many of the cases in which extensive and uniform cheesy deposits are found in the lungs depend more upon chronic catarrhal, or a low and unhealthy type of the inflammatory process, or even scrofulous inflammation of the part, than upon true tuberculous formation.

We have to decide whether these latter are simply inflammatory, or truly tuberculous—or whether they may become one or the other. My own opinion is that there is no difference between the two forms of the disease, except their location and size, and that large yellow tubercles are always mixed with the débris of epithelium, mucus, pus, exudation-globules, etc., in the lungs.

Virchow throws no light upon the point why miliary tubercle is formed in the connective tissue; but this substance is one of the few membranes of the body which contain *casein*. On the authority of Lehman of Leipzig, and Day of Edinburgh, it may be stated that casein exists normally in the expressed juice of the connective and elastic tissues. And here we hit, perhaps, upon the first link in the long chain of facts which go to prove the connection of caseous degeneration with tubercle; and we almost immediately find another, viz.: it frequently happens that the albumen in the parenchymatous fluid or plasma which moistens and nourishes all the tissues, assumes a *casein-like* character; *i.e.*, it does not coagulate on heating, is precipitated by dilute acetic acid, and separates in the form of a superficial membrane on evaporation. Hence the fluid which bathes the connective tissue, and nourishes the connective tissue corpuscles, always is somewhat, and may easily become abnormally *caseous*.

These points may also throw some light upon the fact that true miliary tubercle is commonly developed in the adventitia or lamina of connective tissue immediately surrounding the blood-vessels. We know that the parenchymatous fluid which moistens and nourishes the tissues transudes through the capillaries—and if that be already too albuminous, or even caseous, a cacoplastic or cheesy material will be poured out into the connective tissue, and may excite it to increased growth and proliferation; each minute newly formed granule or cell being made up of caseous material, instead of the more gelatinous and fibrous substance which goes to form true healthy cellular or connective tissue.

But cheesy transformation is not peculiar to tubercle; for it is well known that extravasated blood may undergo it; effusions of all kinds, both exudative and inflammatory; epithelium, newly formed cells, connective tissue corpuscles; and all the albuminoid constituents of the blood, such as albumen, fibrin, globulin, etc.; pus, too, often becomes cheesy, and even cancer and sarcoma occasionally. Hence the time seems to have arrived when we must perforce admit a caseous or cheesy transformation or degeneration of many tissues and exudations, just as we have long ago admitted a fatty degeneration, an amyloid transformation, a fibroid conversion, and saccharine, lardaceous, and waxy metamorphoses.

This theory of caseous degeneration has been progressing slowly in the minds of the profession for many years. Over 25 years ago, Rokitansky was teaching that many abnormal products and exudations, which were not absolutely and evidently tubercular at first, soon began to tuberculize and assume the appearance of yellow or caseous tubercles.

For a long number of years before 1857, the celebrated Dr. Addison, of Guy's Hospital, was strenuously opposing the idea that all, or much of the deposit found in phthisical lungs should be called true tubercle.

Addison's successor, Dr. Wilks, Lecturer on Pathology and Curator of the Museum of Guy's Hospital, continued from and after 1857 to teach that soft, yellow, caseous matter was often undoubtedly produced without being preceded by crude tubercle, and was merely a degenerative change, which even simple substances of a fibrous or cellular character might pass into. He thinks, however, that miliary tubercles are quite distinct in formation and character, and not merely in location and size, from the soft yellow tubercle; but correctly states it is this latter product which is most important in phthisis (simply because it occurs in larger masses and greater quantities). He even goes so far as to assert that, in speaking of the ordinary disorganizing processes seen in phthisis, he will entirely dismiss miliary tubercle from consideration, and look to the (caseous) material which he thinks is all essential in the various phases of the disease.

We all know that our own Dr. Swett, who is certainly held in affectionate remembrance by many who are here, taught long before 1853 that tubercles were generated in pleuritic exudations and adhesions, and he often tells us in his writings that we will fre-

quently meet with tuberculous disease of the lungs which has followed an attack of pleurisy, and is secondary to it.

The views of all these men, and of Virchow, Reinhart, Villemin, and others, made but little impression upon the profession at large, until Viemeyer sprang almost like a harlequin into the medical arena, declaring that the greatest danger for the majority of consumptives is, that they are apt to become tuberculous.

We now propose to examine whether we may or must admit a caseous dyscrasia or degeneration of many tissues, products, exudations, cells, &c., just as we have long ago accepted the reality of fatty degenerations, amyloid degenerations, saccharine transformations, and lardaceous and waxy changes.

The best chemical analyses of tubercle quite distinctly corroborate some of the so-called modern views; and they have this great advantage, that they were made long before any theory was at stake upon their results. Thus the accurate Hasse, who drew his conclusions from his own experiments, and from numerous analyses carefully compiled from Cerutti and Vogel, found the organic component parts of tubercle to consist principally of *casein*, with some little fat and albumen.

As regards casein, we know that the primitive food of all young mammals, viz., milk, contains casein, which is readily transformed into the albumen of the brain, liver, kidneys, and other albuminous organs; and into the musculo-fibrin, or syntonin, which go to make up the extensive muscular system; and we now know that these substances are often transformed back again into casein.

It is true Virchow thinks that the casein of milk is formed from the epithelial cells which line the lacteal ducts. These are supposed to be made in enormous quantities during lactation, are transformed partly into casein, and partly into fat, and then are generally swept out by the gushing tide of fluids pushing behind them. Occasionally they are plastered and occluded in the milk-ducts, just as caseous or quasi-tuberculous deposits often are in the air-cells and smaller bronchi, which, it is well known, are as abundantly supplied with epithelium as the milk-ducts.

Casein is also a highly sensitive substance to chemical reagents, often undergoing decided changes from the application of the mildest of them.

We know that gelatine, albumen, and fibrin may be formed out of casein, and we are also sure that the major part of the tissues and parenchyma of the various organs are made up out of gelatine, albumen, and fibrin; but none of them are composed of unchanged casein. Casein is a foreign and inimical substance to them. Hence we are almost justified, at this early stage, in concluding that disease may arise from the formation and deposit of a cacoplastic lymph, largely made up of casein, or at least of one which soon, and readily, undergoes caseous degeneration, and that this constitutes the essence of scrofula and tubercle.

If we look for the origin of this caseous substance, our attention is at first drawn to the globulin of the red blood-corpuscles. These globules contain nearly 300 parts in 1,000 of globulin and cell membrane; and globulin is a substance approaching so nearly in properties to casein, that the great Berzelius called globulin the casein of the blood. The almost equally well-known physiological chemist, Schmidt, also calls hæmato-globulin blood-casein; and our Dr. Draper says, globulin is a substance approaching so nearly in properties to casein, that we may without much presumption infer that it can easily be converted into it.

Now we know that in the circulating blood there are continuous endosmotic currents between the serum, or so-called intercellular fluid, and the viscid red liquid which occupies the interior of the blood-cells. Hence we are almost prepared to concur with Panum, Moleschott, Has, etc., that casein is a normal constituent of the serum of the blood, and to infer that it may occur in an excessive quantity in the tuberculous or some other dyscrasia.

Again, it is well known that the iron of the blood is deficient in phthisis; and it is equally true, though not equally well known, that a considerable quantity of the fatty matter contained in the blood is contained in the blood-globules, which in their dry state should contain, according to Lehman, from two to three per cent. of fat. Hence if the globulin of the blood-globules contains too much casein and too little fat, the normal transudations and the abnormal exudations may easily undergo a cheesy degeneration.

As the predominating ingredients of the blood-globules are globulin, fat, and hæmatin, and all of these are defective and deficient in tuberculous blood, we would naturally expect to find some alteration or defect in the shape and conformation of the blood-globules in phthisis. The well-known Dr. Theophilus Thompson, Clinical Lecturer at the Brompton Hospital for Consumptives, has paid particular attention to this point, and I show his drawings of the alterations which the blood-globules undergo in phthisis.

It is well to add, that in phthisis the red globules may diminish in number from 130 to 78, and the white globules be much increased, so that a peculiar state of the blood, resembling that which obtains in leuchæmia, or immediately succeeds digestion, when many lymph-globules have been quickly poured into the blood, is often found in phthisis.

If the blood-globules are defective in phthisis, so is the serum of the blood. We have already seen that too much casein and too little fat is returned to it from the blood-globules.

The water and albumen of the serum are also in excess, and the albumen is defective in quality, being less capable of being oxidized or transformed into fibrin, and doubtless more easily convertible into casein. According to Aitkin, this defective albumen in the blood of phthisical persons may increase from 76 to 100 parts in one thousand.

In phthisis we also have a blood which is less alkaline than it should be; the serum may be so feebly alkaline that it often becomes turbid from the presence of very small dark molecules of a protein body, because the albuminate of soda in the blood has been deprived of some of its alkali, and a portion of the albumen thus freed from its soda separates in a molecular form.

Finally, it is equally well known that the normal fluid of the blood-globules naturally contains a great preponderance of the potash salts and phosphates, while the plasma or serum has the greater part of the soda salts, especially the phosphate and chloride of sodium—all these are deficient, and this accounts for the feeble alkalinity of the blood in phthisis.

To sum up:—The albumen and water of the serum are in excess in phthisis.

The fat and iron are deficient.

The alkaline salts are deficient.

The serum-casein is in excess.

When this state of the blood obtains, a too caseous serum may be supplied to the connective tissue, followed by the caseous degeneration and proliferation that Virchow places so much stress upon; and thus miliary tubercles may be formed.

Or a caseiform, too albuminous, or too little plastic

or fibrinous substance may exude silently and slowly, in a very insidious manner, into the air-cells and smaller bronchi, etc., and yellow caseous tubercle may arise.

Or, under the influence of a slight or severe cold, or bronchitis, or catarrhal pneumonia, exudations may take place in the lungs, air-cells, and bronchi, which may quickly undergo the yellow tuberculous or caseous degeneration, together with the epithelium, mucous and exudation corpuscles, and other substances found in them.

Thus we may have the combined local and constitutional origin of tubercle.

Away back, as far as the times of Baillie, tubercular disease was supposed to arise from an infiltration of an excessively albuminous fluid, of a thick or synovial-like character, which then gradually degenerated into a fine granular mass, which also included portions of lung tissue when it softened down into pus.

And we have seen the so-called modern views really differ very little from this; if we substitute casein for albumen, all the rest of the theory may remain nearly unchanged.

The correct treatment of tuberculosis flows easily and naturally from the above views. Fatty substances; alkaline remedies, especially the phosphates of soda and potash; iron, especially in the form of the phosphate or iodide, and the avoidance of an excess of albuminous and caseous substances, especially skimmed milk, must always form the basis of our remedial means.

III. Remarks by James R. Leaming, M.D.

If it can be shown that Niemeyer's doctrine of bronchial hemorrhage, as a cause of phthisis, is not based on truth, then the more important theory of catarrhal pneumonia is equally invalidated and falls to the ground.

I can truly say with Dr. Clark, that I have yet to see the *first case* of bronchial hemorrhage, with the exceptions named (disease of the heart, hysteria, or emphysema), in which I did not or could not at the time of the bleeding clearly discover the phthisical cause.

The experience of many observers who have been careful in the study of facts goes to show that a bronchial hemorrhage will not take place without a cause; and individual assertions to the contrary need to be supported by facts, and as they are not in this case, we must deny the assertion of Niemeyer, "that bronchial hemorrhage occurs oftener than is generally believed in persons who are not consumptive at the time of the bleeding, and who never become so."

About one-third of the cases of phthisis, in the class of chest diseases at the Demilt Dispensary, under my charge during nine years, had early hemoptysis, but never a case of hemoptysis without discoverable cause.

The assertion of Niemeyer that "both events spring from the same source—from a common predisposition on the part of the patient both to consumption and to bleeding," is entirely devoid of point and force, for who ever saw a case of predisposition to bleeding without some cause?

I deny that bronchial bleeding is ever of itself a cause of consumption; for if so, it would sometimes be so in diseases of the heart and hysteria, &c.

The acceleration of the fatal disease depends entirely upon its management. If the hemorrhage is copious, and is not interferred with, it will almost certainly arrest progress of active disease.

I have been asked, What should a physician do when called to a case of hæmoptysis? And I have answered, let him hold the basin; that will keep him from mischief in the way of giving medicine. The patient, seeing the physician confident and cheerful, will become assured, and the emotion of fear will subside; the heart will cease to pump blood unduly into the lungs, and when the conservative act of the hemorrhage is accomplished, it will cease of itself. If the after-management be rational, the immediate benefit of a copious hemorrhage in early phthisis, will be evident to the patient as well as to the physician.

Death from hemorrhage in early phthisis is possible, only when there is a cavity of some size at the root of the lung, or wherever there may be an artery eroded of considerable size. In such cases, too, the cavity is generally of recent formation, for in old cavities the arteries crossing them become impervious. If the cavity be small, the patient may be finally exhausted by frequent bleedings; but generally the patient is dead before the physician sees him. The physician, when called to a case of hæmoptysis, should auscultate his patient in the first instance, and if he finds no cavities, or those only in a part of the lung not likely to be crossed by large arteries, he will do his duty by assuring his patient of the absence of danger.

I firmly believe, because I believe physical signs, that tubercle may be absorbed, never becoming active, and for the same reason, I believe that, after the disease has become active, it may be arrested and its effects be nearly or entirely removed. I believe, from the evidence of hearing a fact, that this may take place without treatment, but more certainly under the influence of proper management.

When the disease becomes active, catarrhal pneumonia is the consequence; Niemeyer mistakes the effect for the cause.

Some authorities state that emphysema and phthisis are never found together; but that is not so. A phthisical patient may become emphysematous; but, if so, there will be arrest of phthisis. Here we have bronchitis frequently becoming catarrhal pneumonia, never producing phthisis, and yet always arresting it when it is developed in a phthisical patient. These are facts that invalidate Niemeyer's doctrines, and they are capable of demonstration in any large clinic of chest diseases.

The expert alone, in the living subject, can diagnosticate the difference between true phthisis and cirrhosis of the lung. In one, there is marked failure of vital power; in the other, it is but little affected. One changes but little after the function of the lung is destroyed; the other improves very much in phthisical signs, as well as rational symptoms, or shows marked tendency to progress downwards. One affects but one lung, the other nearly always affects both. I have found cirrhosis of the lung more frequently among German patients than other nationalities;—is it possible that this fact may have been the foundation of Niemeyer's error? I cannot understand that inflammation, either general, chronic, or interstitial, should be destructive of tissue; but abscesses or gangrene may be a result, if nutrition of a part be cut off.

Niemeyer says:—"The term tuberculization, which has been productive of great confusion, and against which I have long protested, has fallen into disuse," &c., &c.

The language in the foregoing quotation expresses the animus of Niemeyer in few words—it is opposite to Laennec. This is the inspiration of all he has to say on the subject of phthisis or its connections. He is not alone in this feeling. Skoda exhibited it years ago, before modern pathology had made any remarkable progress. Skoda might have led the way, after Laennec and Louis, in directing the *study* of facts connected with diseases of the chest, basing it upon the science of acoustics. He discovered the fact of conso-

nating sounds in explanation of certain chest signs. But his eager desire to be opposed to the great founder of physical diagnosis blinded his eyes, and he missed his opportunity. He took no advantage of his discovery, and there it still remains, a single isolated fact—the key indeed to a world of exact knowledge on this subject, but left for development to other hands.

A student in the Charity Hospital of Paris, after a few years of devoted clinical study, discovered mediate auscultation, and in 1819 published the result of his studies, with an account of his great discovery. Seven years later he published his second work, the result of all his investigations, and then went to his country home to die of that disease he had done so much to render comprehensible by all succeeding observers.

These few years of study changed the thought and practice of the medical world in regard to the most fatal disease of mankind. This knowledge opened to us, like all true and valuable learning, is progressive, and every year has added proofs of our indebtedness to the great discoverer.

Modern pathology is yet in its infancy. When accounts of new discoveries are looked for with almost as much eagerness as for war bulletins,—when the news of the discovery of Colnheim divides the attention with that of the fall of Napoleon III., it is seized upon and brought out as demonstrative evidence against all the teachings of Laennec.

It is unfair to compare the pathology of fifty years ago with that of to-day, for the advance of knowledge since then has been marvellous. The memory of Laennec does not live as a pathologist, but as an auscultator. He accepted the pathology of Bayle on tubercle, he did not originate it; but what evidence in our knowledge of tubercle have we beyond what was known by Laennec? Virchow and Niemeyer admit miliary tubercle; all the difference, then, is in the consideration of what Laennec called yellow tubercle, and modern pathologists call caseous metamorphosis.

As earnest physicians, seeking only the truth, and the best interests of our patients, we will not follow, blindly, theories projected either by Laennec or the modern pathologist. The great benefit Laennec has conferred upon the world is a clear and certain diagnosis of phthisis at its earliest commencement, as well as in each stage of its course, either to a fatal end or to arrest of progress and possible repair.

There may be differences of opinion as to pathological changes, and in the present progressing condition of our knowledge, this must be so till perfection has been reached. There may be differences as to the best therapeutical means to be used for cure, and each may have measurable success looking to the same end; and the same with prophylaxis. But to honest inquirers, there can be no differences of opinion as to the value of early recognition of morbid structural changes in the lungs, so that whatever is to be done may be done in time.

Is there a pretubercular state, or, for the sake of argument, a prephthisical state?

Dr. Edward Smith has gone particularly into this question, and I agree with him in his general hypothesis; but if I understand him rightly, most of the cases he describes as pretubercular are already tubercular, that is, there is already a deposit of "materies morbi" in the lung structure, that, if not properly managed, will end in structural death of the surrounding tissues.

The expert ear alone can recognize this fact with certainty, and yet the rational signs are almost unmistakable. The history of the patient will throw much light on the subject, and to make this available we must be alive to the value of remote or predisposing causes.

Nearly all observers have recognized the fact of inherited tendencies. Children of phthisical families are more liable to the disease, under depressing circumstances, than those not phthisical. There are many exceptions to this rule, but they do not invalidate it.

It is also known from experience that depressing agencies and conditions are liable to be followed by phthisis, especially when there is an inherited tendency. Want of food, or improper food—either non-supporting or over-stimulating—bad air, depressing emotions from any cause, exhaustion from study or mental work, confinement in dark rooms, employments requiring positions of the body interfering with expansion of the lungs, pleuritic adhesions, preventing proper aeration of the blood and causing continued systematic irritation and functional disturbance—I believe this is a frequent and often overlooked cause, and a remedial one—suppression of the menses in certain cases, excessive venery or self-abuse, or any cause or any state which depresses the organic life, is apt to induce phthisis, more especially when there is a family tendency.

These facts are corroborative of the doctrine of tubercle as the first morbific presence. Virchow describes it as the meanest of animal products, and Dr. Clark long ago described it as having but little life, and rapidly going through morbid changes; and all history of it shows it as a neoplasm of poverty which takes advantage of a lowered state of the organic life to make its appearance. From knowing these facts we have the rational prophylaxis to avoid tubercle or prevent destructive change; to keep the system above par by means and conditions opposite to the recognized causes of depression. Out-door exercise and regular vigorous exertion, proper food in proper kind and quantity, and frequent expansion of the chest and forcible dilatation of the lungs in every part, change of air and food, freedom from care, with pleasing occupation, is rational prophylaxis, and useful in treatment. Medicines that support and corroborate the organic life of the body, relieving the body of depressing agents or causes, by improving the digestion by whatever means, is the treatment we have learned from experience. Is this baneful, as Niemeyer states the prophylaxis and treatment based on Laennec's views to be? Has not experience proved it to be right, and that the proper management of early cases either with or without inherited tendencies is eminently successful?

In conclusion, the doctrine of Niemeyer will not bear close examination, for it is false in fact and dangerous in practice. For mere theory it counsels us to throw away the result of fifty years of valuable experience of many observers, and to leave the progressive system which is leading us year by year to better and better results, and to go back again to the opinions and practices of a system already proved to be unsuccessful in practice, merely to indulge a whim of opposition to Laennec.

IV. Remarks by Wm. M. Chamberlain, M.D.

Without any previous intention of speaking on this subject, I will, for a moment, call attention to the radical change in our opinions, not only as to pulmonary phthisis, but as to almost every form of disease to which the views presented and accepted by Dr. Draper conduct us.

In each of his papers he attaches great weight to the inoculation-experiments of Waldenburg, Clark, Sanderson, Fox, and others.

According to these observers, the introduction into the areolar tissue, not only of morbid animal products,

but of mineral and vegetable substances and chemical compounds, results, with surprising constancy, in the production of tubercles in the lungs and other internal organs.

Thirty-four out of one hundred and four inoculations made by Waldenburg, of the most diverse, and in some cases the most innocent, substances, are said to have been followed by tuberculosis.

I do not recognize in these inoculations anything differing from the practice of vaccination or hypodermic medication, or the use of a seton, or the innumerable test inoculations of the products of constitutional syphilis made by Ricord, which I have personally repeated in hundreds of instances.

From this point of view what is to be said of Prof. Boeck and Auzias Turenne?

It is a new and demoralizing view of our responsibilities, if, with every third repetition of these acts, we have set up tubercular phthisis.

Moreover, these experiments are forced, not without hesitation it appears, to say that any and every form of inflammation of the skin and mucous surfaces, or of the connective and glandular tissues beneath them, are, in alarming degree, likely to end in tuberculosis of the internal organs.

When we consider the series of injuries, exciting more or less local suppuration, and the forever-recurring catarrhs of one or another mucous membrane, to which we have been subject from our youth up, it is matter for wonder that we are any of us here to listen to this discussion.

These observers are in conflict among themselves; Waldenburg and Fox assert what Villemin denies.

These facts, if they are facts, are broad, simple, and palpable, requiring no recondite methods for their detection. It is hardly to be credited that they should have escaped observation so long. They seem in conflict with the vast aggregate and common experience of the profession, and it is much more easy to my mind to believe that there is some fallacy lurking in them, than to accept them in the sense in which they are propounded.

Dr. Draper stated, in reply to Dr. Chamberlain, that there were marked distinctions between the inoculation experiments which produced artificial tuberculosis and the practice of vaccination, of hypodermic medication, and the inoculation of syphilis. In the former, the substances inoculated all presented a common physical property, namely, the presence of minute corpuscular elements or purely divided solid matters. In the latter, the materials inoculated are either a virus which cannot be demonstrated by the microscope or chemical analysis, or a medicament which is held in solution and is directly absorbed into the vascular or lymphatic circulation. It is true that where vaccination is practised with the crust, the conditions might be regarded as the same that are presented in the tubercle inoculations; and Niemeyer is disposed to question the propriety of vaccination in weakly children, on the ground that it may give rise to tuberculosis. In regard to the objection that setons are often used, and abscesses and tegumentary inflammations are of common occurrence without the sequences which were observed in the tubercle inoculations, and that therefore the explanation which has been given of the production of tubercle by a resorptive process is not tenable, we can only say, that the explanation is the best that can be given at present, and that the objections to it would be equally sound if made against the ordinary theory of pyæmia.

Dr. Draper further remarked, in regard to Dr. Leaming's paper, that the Doctor seemed to exhibit much the same sort of animus towards Niemeyer that he charged Niemeyer with entertaining towards Laennec. He thought it hardly fair to charge Niemeyer with a spirit of partisan opposition in matters of science, especially as the views which he expounds in his masterly work on the Theory and Practice of Medicine are based upon the most recent discoveries in pathology, and upon a large personal experience. In regard to Niemeyer's doctrines of the relation of pulmonary hemorrhage to phthisis, Dr. Leaming certainly does Niemeyer injustice in saying that his views upon this subject have no other foundation than pure dogmatic assertion. Niemeyer, in his monograph on pulmonary phthisis, cites some striking cases in support of his view that hemorrhage is sometimes the antecedent of pulmonary phthisis. The physical evidence upon which Dr. Leaming lays so much stress, as proving in his own experience that a pulmonary lesion can always be found in cases of hæmoptysis to account for the hemorrhage, is certainly capable of a different explanation from the one he would give. The presence of blood in the bronchial tubes and pulmonary alveoli, must modify the normal physical conditions, and might easily give rise to the evidences of consolidation and the presence of râles, which Dr. Leaming would consider signs of previous disease. That this is a reasonable hypothesis is rendered more probable by the fact, which all clinical observers must admit, that these signs are often transient and disappear with the recovery of the patient.

He remarked, in conclusion, that the value of physical diagnosis in phthisis is often exaggerated. Tubercles, in their isolated form, are not always revealed by physical signs, as experience in acute miliary tuberculosis has often demonstrated. The so-called deposits of tubercle which are discovered by physical signs, are simply localized condensations of lung tissue produced by a variety of causes, so that it is as irrational to attempt to diagnosticate tuberculosis in its early stages by physical signs alone, as it would be to determine the nature of a cutaneous disease solely by the appearances of the lesion.

On motion, the Academy adjourned.

Original Communications.

CASE OF ERECTILE TUMOR CURED BY ELECTROLYSIS.

By R. P. LINCOLN, M.D.
NEW YORK.

Gen. K——, aged 33 years; weight about 135 pounds; light complexion; nervous and excitable temperament; has never suffered from sickness, except that consequent upon wounds received while in high and active command in the army during our late war, and from which he quickly and completely recovered. After the close of the war he engaged extensively in public speaking, and to this he attributes his present trouble.

In April, 1869, immediately after a special effort at public speaking, he experienced a pain in the neck where there is now a tumor; this continued constantly for a few days when it remitted, to be reproduced by exercise or much speaking. Six weeks later he discovered a tumor, which was then quite small. In December, the tumor having increased in size from the first, he resorted to a system of water treatment, sulphur baths, cathartics, and tincture of iodine locally, till he could not walk from weakness. This exhausting process so much reduced the tumor that it was not

noticeable, but it reappeared as he regained his former strength. Last February he again resorted to treatment—viz., ice constantly applied to the tumor, leeches to the anus, mustard to the feet, and powerful cathartics repeated twice a day. After two weeks of such treatment he was again so much reduced that he could not speak from weakness, but the result was the same as before.

On the night of July 4th, he gave a public reception, the excitement of which caused so great an enlargement of the tumor that he was obliged to withdraw on account of the severe pain, sense of suffocation, and loss of voice; for three days, during which death seemed imminent, these symptoms persisted, notwithstanding every effort of the attending physicians, when they finally yielded to the same remedies that had succeeded before. The increasing frequency of these severe attacks, and his alarm at the increase in the amount of his constant suffering and the size of the tumor itself, compelled him to resign his position as Minister to a foreign Court.

On examination with the neck completely exposed there was presented on its left side a tumor occupying the antero-inferior portion of the region defined by the sterno-cleido-mastoid and trapezius muscles and the clavicle. It was uniformly rounded in shape, two inches in diameter, and at its apex rose five-eighths of an inch above the natural contour of the neck. The sterno-cleido-mastoid muscle was more prominent on this side than on the other, and the trachea was crowded one-half of an inch to the right of the median line. To manipulation the tumor was elastic and readily compressible, but when pressure was removed it immediately resumed its former size and shape. The tumor possessed no pulsation of its own; there was transmitted pulsation from the carotid beneath. Pressure applied to any one spot would neither increase nor diminish its size. It was well defined superiorly and posteriorly, but inferiorly it extended somewhat below and behind the clavicle, while anteriorly it embraced the edge of the sterno-cleido-mastoid at its lower quarter. The integument was of normal appearance and entirely free from the tumor. During the act of swallowing it moved synchronously with the trachea, but not quite to the same extent. The whole size of the growth seemed to be as large as a large goose's egg. Anything that interfered with the circulation, as indigestion, or when it was accelerated by the emotions or by exercise more active than usual, it might be increased to twice its usual size. If he held his breath and at the same time made an expulsive effort the tumor would become immediately distended, as well as the veins of the neck and face. If he lay with his face down, the same condition presented. If from any cause the size of the growth was temporarily increased, he suffered much pain, which often extended up the neck and to the head, and at the same time he experienced a sense of suffocation and would occasionally lose his voice. The excitement of delivering an address would induce these same symptoms to such a degree that he was forced to decline every effort of the kind.

The growth was diagnosticated as venous erectile and its treatment by electrolysis recommended. The patient was advised to consult Dr. W. A. Hammond, who confirmed the diagnosis and approved the recommendation.

September 30th.—After many preliminary experiments I performed the following operation, using a battery* devised by my associate, Dr. L. F. Sass, who shared with me the responsibility of the case. There were also present Drs. W. A. Hammond and C. E. Hackley, who kindly rendered assistance.

The patient having been chloroformized, I introduced four gilded steel needles, insulated to one-half or three-fourths of an inch from their points, into the four quarters of the tumor, the two upper being one and one-fourth inch apart and one inch above the lower, which were one inch apart. The two inner needles were connected with the subdivided anode, and the two outer with the subdivided cathode, and ten elements of the battery, which was working with a weak current, connected within a few moments, and gradually the power of the battery was increased to its maximum, and the number of elements increased to fifteen. At the expiration of fifteen minutes the two lower needles were disengaged from the current, thus concentrating the whole force upon the two upper; at the expiration of fifteen minutes more the needles were removed.

During the operation all the prominences of the tumor disappeared, and a delicate examination detected a hard mass in its place. Not a drop of blood escaped on the removal of the needles. The skin over the tumor presented a bright blush, and the trachea had returned towards its proper position.

Quiet was enjoined upon the patient, and the only application was a cold-water compress. The soreness, which was considerable after the operation, had so far passed away that at the end of three days he was walking about his room, and on the fifth day he left the city, relieved from all unpleasant symptoms and positive in his own mind that he was entirely well. The neck at that time presented no tumor, and the trachea had returned to its normal position.

October 10th.—Patient presented himself for examination. There was no tendency to a reappearance of the tumor; on the contrary, the induration in the neck was steadily diminishing in size.

October 22d.—The following is an extract from a letter from the patient, who had already made several addresses: . . . . "I am feeling very well and there is nothing to indicate anything like a recurrence of my malady."

* A full description of this battery will appear in a future number of this journal.

Progress of Medical Science.

NON-OVARIAN MENSTRUATION.—Dr. A. Reeves Jackson, Chicago, Ill. (*The Chicago Med. Journal*), narrates 8 cases of non-ovarian menstruation, which Spencer Wells has proposed to distinguish from menstruation by the terms "Uterine Epistaxis," or "Metrostaxis." If credence is to be given to the prevailing theories of menstruation, it seems to be admitted that the presence of the ovaries and the process of ovulation are not the *only* things necessary to menstruation, or the menstrual molimen; that the lining membrane of the cavity of the uterus is not the *only* source of the menstrual discharge; and that the "ovulation" theory must be either materially modified or else discarded as not sufficient to account for all the phenomena.

THE FIRST RECORDED CASE OF A WOUND OF THE PERICARDIUM.—The first wound of this character dates from the time of Benivenis (who died in 1503), and Cardenas, who, in 1501, recorded a reliable case of cure following a wound of the pericardium, with loss of substance. A case of penetrating wound of the heart was first described, with a microscopic examination, by Ambrose Paré.

FIVE HERMAPHRODITES.—Dr. B. Rush Bateman, of Cumberland County, New Jersey (*Trans. Med. Soc. of N. J.*), was present at five successive births in one family, where each child was a hermaphrodite, partly composed of both sexes, especially the genital organs. In every case there was a penis and vagina, in two of which there was a sac on each side of the vagina externally, with a testicle in each. It was exceedingly difficult to classify the sex in such cases. In one case, the sexes were so well defined, that it was finally concluded to class it with the males; it was called Charles. As it grew older it wanted a doll, needle, and thread; its name was then changed to Charlotte. She is now living and healthy, and about thirty years old. Her features are coarse, voice more masculine than otherwise; but she is smart and active, and remarkable for her sagacity at housewifery; does not mix with either sex to any extent.

All of the five were healthy children, and lived to grow to maturity; all are now living but two. One was married, but he never had any issue.

BROMIDE OF POTASSIUM IN LEUCORRHŒA.—Dr. A. H. Kinnear, Metamora, Illinois (*Chic. Med. Journ.*), has given, with success, in twelve marked cases of vaginal or uterine leucorrhœa, none of which were of less than six months' standing, bromide of potassium. The majority of the cases yielded to the treatment in four weeks. He has observed two effects from the use of this drug: the alterative and nervo-sedative.

A REMEDY FOR ASTHMA.—Dr. James S. Bailey, of Albany, says:—Having during the last fifteen years prescribed many of the remedies mentioned with indifferent and uncertain success, after much careful study I have prepared the following formulary, which has, during more than half this period, acted to my entire satisfaction. I now place it at the disposal of the profession, hoping it may meet with the same success in their hands as mine, in relieving the distress of this unfortunate class of sufferers.

It is as follows:—

℞. Syrup of tar compound.. ℥ iv.
Sulphuric ether..... ℥ ii.
Pulv. gum acacia..... ʒ vi. M.

Take one teaspoonful every two or three hours until relieved. Oftentimes two or three doses are quite sufficient to relieve an aggravated attack of spasmodic asthma.

As the syrup of tar comp. is my own preparation and not pharmaceutical, it is necessary to give the formulary for its preparation, which is as follows:—

℞. Picis liquidæ..... ℥ iv.
Scillæ acet.....Oj.
Antim. et potass. tart..gr. xvi.
Magnesiæ carb..... ℥ ss.
Sacch. albi..... ℥ xxx.
Sulph. ether,
Spts. vini rectificati, āā..f. ℥ j.

Mix the tar and carb. magnesia intimately in a mortar, adding the alcohol first and then the ether, then add the acet. scillæ and throw the whole upon a stout filter. Having added sufficient acet. scillæ (if may be) to make the filtered liquid measure Oj., proceed to make the syrup by the usual U. S. P. formulary, taking care to apply a gentle heat. Lastly, strain through flannel and add the tart. antimonii in solution.

After the paroxysm is relieved the patient is left in a relaxed and debilitated condition; it is then necessary to resort to a tonic course of treatment. A generous diet, with simple bitters or some mild preparation of iron, is generally sufficient to restore the system to its accustomed health.

TREATMENT OF GONORRHŒA WITH TANNIN AND GLYCERINE.—Dr. Schuster states that tannin mixed with glycerine at first forms a soft, waxy substance, which soon becomes hard and brown, and melts in a moist atmosphere at the temperature of the body. Dr. Schuster has formed small pencils of this compound, which he inserts into the urethra of patients suffering from gonorrhœa. He has found the treatment by means of caustic injections (the abortive method) frequently to fail, and that it occasionally produces violent pain, inflammation, and hemorrhage. On the other hand, the treatment with slightly astringent solutions cures the gonorrhœa within a period varying from four to seven weeks, but is often followed by a troublesome gleet. The tannin-glycerine rods employed by Dr. Schuster are from three to four inches in length, well rounded at the extremities, and consist of thirty grains of tannin, one grain of powdered opium, and a sufficient quantity of glycerine to form a pastille. These rods are hard in winter and soft in summer. Before their introduction, they should be dipped in warm water. They are to be left from five to ten minutes in the urethra, and then withdrawn. As a rule they produce no pain. If, however, they be left in for an hour or for a night, more or less pain is caused, and this appears to be due to a combination occurring between the tannin and the mucus or pus, which becomes hard and acts like a foreign body. Dr. Schuster has had no case of orchitis following the use of these pencils, though he has thought it advisable to recommend the employment of a suspensory bandage, nor has he noticed any irritation of the bladder or prostate. In cases of gleet, a rod may be left in for a few minutes, and a speedy cure usually results.—*Lancet.*

AMMONIA HYPODERMICALLY IN COLLAPSE FROM UTERINE HEMORRHAGE.—Dr. E. G. Wake (*Richmond and Louisville Med. Journ.*) reports a case of collapse from the above cause, in which the pulse was not felt at the wrist for more than an hour. In his eagerness to apply a powerful remedy, he injected a few minims of strong liquor ammonia over the sternum. The operation was repeated three other times upon other parts of the body, from 10 to 20 minims being used at each injection. The patient rallied immediately and made a good recovery. Four frightful sores followed the treatment.

STARCH, GLYCERINE, AND CARBOLIC ACID is an excellent preparation for healing ulcers and for promoting healthy granulations on wounded surfaces. It is made by heating the glycerine to a boiling temperature, then adding the starch in fine powder, slowly—stirring the mixture for a few minutes or until it is brought to the consistency of a soft paste. Then allow it to cool, after which add a small quantity of carbolic acid, and mix thoroughly.—*North-western Med. and Surg. Journ.*

THE SYPHON INSTEAD OF THE STOMACH PUMP.—Dr. J. T. Hodgen (*St. Louis Med. Journ.*), instead of the ordinary stomach pump or a Davidson's syringe attached to a gum elastic catheter, uses the following apparatus: he attaches four feet of rubber tubing to a stomach tube. Fill both with water by simply dipping it in the liquid end first, then, compressing the elastic tube between the fingers to keep the fluid from running out, introduce the stomach-tube, lower the outer end of the elastic tube, and the contents will pour out as readily as from an open vessel. When the fluid ceases to flow, dip the outer end of the tube beneath the surface of the water, elevate the vessel containing it, and the stomach is soon filled; lower again the outer end of the tube and the stomach is again emptied. This may be repeated as often as necessary.

Iodized Milk.—It is well known that milk takes up iodine, disguising its taste, smell, and color completely; since iodine is an antiseptic, iodized milk keeps for some time. Dr. Hagar calls attention to this fact, and suggests that this, perhaps, is the mildest form of administering iodine. Its therapeutical effect seems to be equal only to about one-fifth of the iodine. He also thinks that iodized milk will soon be a favorite form of administering iodine, and suggests the following mode of preparation: Iodine 1 part, dissolved in 10 parts of alcohol, with 90 parts of fresh warm cow's milk.—*New York Medical Journal.*

Odontalgia.—Dr. H. T. Reynolds writes to the *Phil. Medical News* as follows: "For eighteen months I have been using acetate of lead for toothache. I find it to act better than any of the numerous remedies proposed in the books, and in cases in which it is applicable the relief is instantaneous. Let the patient apply one or two grains to the cavity and then spit it out. It fails in fewer cases than any remedy I have tried."

Veratrum Viride as an Antidote to Opium.—Dr. E. H. Sholl communicates (*Phil. Med. & Surg. Rep.*) a case of poisoning by morphia, which was cured by veratrum. The patient, a negro, aged fifteen years, had typhoid fever, and took an overdose of morphia, which had been prescribed for hiccup. It was followed by all the symptoms of poisoning by this drug. Gtts. xviij. of Norwood's tincture were administered, with two ounces of brandy. In an hour all the symptoms of poisoning had vanished.

Congenital Gangrene.—Dr. J. R. Bratton (*Richmond & Louisville Med. Jour.*) presents an interesting case of this disease, which came under his observation. A lady, about twenty-five years of age, was delivered, after a natural labor of three hours' duration, of a well-developed female child, healthy in all respects, except the left hand and forearm, which presented the following condition. Upon the palmar and dorsal aspect of the hand, as well as the flexor and extensor surfaces of the forearm, about its middle third, were patches of skin and subjacent cellular tissue, irregular in form, and about an inch or more in diameter, in a gangrenous condition. Those portions of the skin between the patches on the hand and those on the forearm were in an erysipelatous condition, as well as that portion of the integument extending from the patches on the arm to the middle third of the humerus. The child was applied to a healthy wet-nurse, and glycerine and carbolic acid lotion applied to the gangrenous surfaces. In a few days the dark livid surfaces cleaned off, leaving healthy granulating surfaces beneath. In course of time the surface was entirely healed.

A New Remedy for Asthma.—A writer in the *Amer. Practitioner* came into the presence of a polecat and the "offensive effluvia arising therefrom." He was at the time suffering from a severe paroxysm of asthma. He had been in the presence of the animal but a few moments when he was entirely relieved of the paroxysm. As soon as possible he procured the musk-bag of one of the animals, and prepared an alcoholic tincture. The scent of this never failed to avert promptly a paroxysm of the disease, and ultimately the remedy, or time, or both combined, effected a permanent cure.

Aphasia from a Shot Wound of the Head.—Dr. W. E. Whitehead, U.S.A., gives the history (*Pacific Med. & Surg. Jour.*) of a case of this kind, where the patient was found wounded by a large pistol ball, which entered the head at about three and three-quarter inches from the eyebrow of the right side, and an inch and a half from the median line. The track of the ball was from before, backwards, and towards the right side. The ball had lodged within the cavity of the skull. It could be traced with the little finger for two and a half inches. The patient could see well; pupils slightly dilated; hearing and taste perfect; no paralysis; deglutition normal. He, however, could make no audible sound, although he made every effort to do so. When wounded, the hemorrhage had been profuse, and during the examination considerable brain matter oozed out, as it did during the night following. The patient got out of notice, and his subsequent history is not known.

Belladonna in Cholera Morbus.—Dr. H. E. Whitehead having had occasion to treat several cases of severe attacks of cholera morbus, and having failed to relieve the first case with opium, ordered for the patient pills containing one-third to one-half a grain of the extract of belladonna; one to be taken every four hours. The first pill relieved the sense of constriction or knotty pain in the region of the umbilicus, and after the third pill the bowels were freely moved, although several purgative draughts had been taken previously without effect. After having taken two grains of the extract the patient rapidly recovered, with no constipation, headache, or unpleasant symptoms. The result in three other cases with the belladonna treatment was equally successful.—*Pacific Medical and Surgical Journal.*

Puerperal Fever Treated by Venous Injection of Ammonia.—Tyler Smith, as referred to in the *American Journal of Medical Sciences*, has treated and cured a desperate case of puerperal fever by injecting ammonia into the veins. He employed about seven minims, diluted with three times that quantity of water. Under this treatment the symptoms of uræmic poisoning disappeared.

Paraplegia from Atmospheric Pressure.—Dr. Louis Bauer reports to the *Chicago Med. Examiner* that many of the workmen engaged in building the Mississippi bridge at St. Louis, and working in an air chamber under water, at a pressure of sixty pounds to the square inch, were stricken down with paraplegia, and that several of them died with inflammation of the brain, cord, or membranes.

Veratrum Viride in Pneumonia.—Dr. T. M. Woodson, in the *American Practitioner*, strongly endorses the use of veratrum in pneumonia. He gives a history of four cases in which he used it in six or seven drop doses every three or four hours, with large doses of Dover's Powder, and sometimes calomel. Some of these cases were very severe, the pulse reaching 132, with the temperature 105°, and the respiration 30 or more. The veratrum brought down the pulse, promptly, sometimes with vomiting and purging, but safely, to from 55 to 70 per minute. The temperature and respiration were promptly reduced, and convalescence was speedily established. The veratrum works more kindly with opium, and these two agents he places at the head of all remedies for the active stage of pneumonia.

Bromide of Potassium in Children.—E. Montord-Martin, of Beaujon Hospital, France, shows the value of this drug in all cases of dentition, where there are aggravating symptoms, and it is improper to give opium. In sleeplessness of infants, in cough merely spasmodic, he gives it in three-fourth grain doses once or twice a day to children from three months to a year

old. In purely nervous cough it is equally indicated; but it should not be given in diarrhœa, as it increases the difficulty. In excessive erethism of any kind, and especially those cases of boys where there is almost constant erection of the penis, it works most happily. When administered to infants, the breast should be given immediately afterwards.

Treatment of Chorea.—The subjoined formulas are recommended by Dr. T. Curtis Smith, Middleport, Ohio (*Cincinnati Lancet and Observer*), in chorea, in conjunction with strong salt baths, attended with much friction:—

℞. Tr. actea racemosæ.....
Tr. hyoscyami..... } .....āā ℥ ij.
Syr. simplic.....

M. S. Tablespoonful every six hours; also

℞. Ferri sulphas.....ʒ iij.
Zinci sulph.....ʒ iss.
Quiniæ sulph.....ʒ j.

M. ft. pil. xx. S. One three times a day.

Ipecacuanha in Dysentery.—Drs. Wright, Mathieson, Gunsolas, and Walton, of the Montreal General Hospital, Canada (*Canada Medical Journal*), publish cases of acute dysentery successfully treated with large doses of ipecacuanha. In these cases strict injunctions were given to use the least possible amount of fluid during the twenty-four hours following admittance into the hospital. The ipecacuanha was given three times daily in powder, in doses of from ten to twenty grains.

An Excellent Aperient in Skin Affections.—Dr. McCall Anderson, of Glasgow (*Lancet*), recommends in skin diseases the well-known sulphate of magnesia and sulphuric-acid mixture, to which, if there is a gouty tendency, a little wine of colchicum, or, if anæmic, sulphate of iron may be added as follows: Sulphate of magnesia, three ounces; dilute sulphuric acid, an ounce and a half; sulphate of iron, three drachms; simple syrup, six ounces; syrup of ginger, one ounce; infusion of quassia to twenty-four ounces; a tablespoonful in water three times daily.

The Sounds of the Heart.—George Paton, M.D., Toronto, Canada (*The Dublin Quart. Journal*), arrives at the following conclusions respecting the sounds of the heart:—The first sound is produced by contraction of the ventricle and impulse of the aorta. It commences as the blood is propelled with force through the aortic foramen, and attains its intensity in the aorta, as the blood is thrown back against the aortic valves, and shuts them on the impulse being imparted to the wave. This sound is heard most distinctly in the denuded heart, over the semilunar valves, at the origin of the aorta, or a little above it.

The second sound depends on the contraction of the auricles, and is produced as they propel their blood with force through the auriculo-ventricular foramen into the ventricle during its dilatation.

It appears to follow the first sound as an immediate sequence, as it takes place so quickly after its completion, but it is the commencement of a new beat, and synchronous with the dilatation of the ventricle, and of course precedes the ventricular systole.

The second sound of the heart is produced by the force with which the blood is propelled by contraction of the auricle, through each auriculo-ventricular foramen, into the ventricles during their diastole.

A bruit sometimes attends one or both sounds, when the action of the heart is weak, and disappears when the action is strong—so that one cause of inorganic murmurs is the want of energy in the contraction of the auricles or ventricles, and whatever restores this removes the murmur.

He states in conclusion, that from the manner in which the first sound is produced, it can be perceived how a murmur connected with the contraction of the left or right ventricle is propagated along the aorta or pulmonary artery; a circumstance on which Dr. Hope laid great stress in determining to which side of the heart the murmur belonged.

Idiopathic Gangræna Genitalia in Infancy.—Dr. Jonathan W. Brooks, of Chicago, Ill. (*Chicago Med. Jour.*), records three cases of this fatal disease, which declared itself without apparent cause in perfectly healthy children; all but one were girls, and all between one and four years of age. These cases seem to have been induced by a septic poison *sui generis*. The two first cases were fatal. The third child is living, and if she recovers fully, it will be the first recovery he has seen from this disease.

An Enlarged Spleen.—Dr. John G. Day, University of Maryland Hospital (*Balt. Med. Journal*), mentions the case of a negro, aged 28, who had been very frequently the subject of bilious and intermittent fevers, and was admitted into the University of Maryland Hospital. The case was diagnosed as one of *enlarged spleen*, with the usual accompanying phenomena, and Dr. Chisolm suggested the removal of this organ; but the patient in moving along one of the hospital passages fell down a flight of steps, and died. An autopsy revealed the following condition:—The weight of the liver was seven pounds three-quarters. The spleen extended throughout the whole of the left side of the abdomen, reaching nearly to the pubes, also encroached on the right side for about two and a half inches beyond the median line. It was lobulated upon the right margin, the fissures being four in number, and from one to two inches in depth. This organ was adherent to the diaphragm. There were also attachments between other parts of the abdominal viscera. The weight of the spleen was nine pounds three-quarters; length, sixteen inches; greatest breadth, eleven and a half inches. Several beautiful casts were taken of the organ, and placed in the Museum of the University of Maryland.

A Fragment of Axe passed per Rectum.—Dr. Stevenson, of the *Cincinnati Academy of Medicine*, referred to an accident to a farmer's boy, who swallowed a fragment, 1¼ inches wide, of a new axe, which came off while chopping wood. Both corners were as sharp as a knife-blade. The piece of steel passed per rectum some three or four days afterwards, attended with pain and hemorrhage. The discharge was assisted by the hand.—*Cin. Lancet & Observer.*

Hæmorrhoids.—In recent cases of hæmorrhoids, Prof. Nathan R. Smith, of Baltimore, advocates this formula:—

℞. Sulphur lot. . . ℥ j.
Fol. sennæ pulv. . ʒ j.
Ol. fœnic. . . . gtt. xx.

M. ut f. pulv. S. Give a heaping teaspoonful every other night. The parts must be bathed three or four times a day with cold water, and especially after stool.

Rarity of Gunshot Wounds of the Heart.—Of 87,822 wounded in the American war, among which are 7,062 gunshot wounds of the thorax, 4,759 wounds of the thoracic walls, and 2,303 penetrating wounds of the chest, there were only recorded 4 cases of gunshot wounds of the heart.

THE MEDICAL RECORD.

A Semi-Monthly Journal of Medicine and Surgery.

MEDICAL MEN AS PUBLIC OFFICERS.

A PROMINENT and respected surgeon of this city, while giving advice to his class at the close of a lecture term, made the broad assertion that any medical man who interested himself in politics did so at the risk of damaging his professional reputation. The opinion was readily accepted by his hearers as orthodox, and, without inquiring into any reasons which the speaker might have had, was received as a ruling decision. The profession at large, for an equally unaccountable reason, have been, in this country at least, of the same way of thinking. The whys and wherefores have not, however, transpired, except that we allow the truth of an assertion too often made, that the individual members of the profession lack the necessary independence of opinion which is the legitimate offspring of individual conviction. As a body, we are so jealous of what we consider our purely professional prerogatives, that in our watchfulness to protect them we lose sight of every other interest. We foster this disposition to such an extent that we become morbidly sensitive, and in our great desire to shun "every appearance of evil," we grow timid in the contemplation of any innovation of the established beliefs and usages. It is enough for the majority to hear it asserted that this or that is wrong, to follow the general current of opinion without the least show of a resistance in the shape of a contrary belief.

We contend that there is no good reason why any and every physician should not interest himself enough in the political questions of the day, to protect his interests as a professional man. There can be no inconsistency in his becoming a politician in this sense, or in his consenting to become a candidate for an office, which, as an educated medical man, he may be fitted to fill. There is certainly enough to be accomplished in our interests to bring the expediency of legislation by medical men, to the serious consideration of the profession at large. There are certain points upon which the medica legislator only can express an intelligent and trustworthy opinion; certain protections, which, as a humanitarian, a scientist, and good citizen, he is eminently qualified to guarantee. It is not only his privilege so to do, but likewise his duty.

We have, from time to time, noted the good results that have attended the well-directed efforts of medical men who have held offices of trust. Although, in consequence of the general prejudice of the brotherhood against the policy of holding such positions, the number of medical men occupying them has been very small, we have had reason to appreciate their great usefulness. They have, with but very few exceptions, commanded the respect and gained the confidence of their associates, and their voices and influence have been proportionately great in stemming the tide of corruption, malfeasance, and quackery. In more than one instance have these medical men in our legislative halls used their influences for the good of the profession, directly, in a manner that no other individuals could. They have acted for the profession as only such can act who have an abiding interest in its present and future welfare. In a word, their brethren have had no occasion to be ashamed of their representatives. In view of these facts such gentlemen deserve more of their profession than a suspicion of being irregular, and as defiant violators of conventionality; more than this, they are entitled not only to countenance, but to hearty support. We see no reason why a good physician should, because of his being such, be a bad legislator; why, in his new sphere, he should not, by the use of this special knowledge, be of extra service to the community at large. We have had numerous examples of this fact in this country, and we can point to physicians who have during the last decade distinguished themselves in almost every department of government, civil and military; but in other civilized countries, in consequence of the liberality of professional sentiment, there is a much greater majority. Particularly is this the case in Great Britain. There, far from its being considered a disgrace to hold a public office, it is esteemed as an honor, which is eagerly sought by well-qualified men. There the profession not only recognize their power and rights, but make them felt. In every question pertaining to medicine, where legislation is necessary, the profession, as a body, are clamorous for their rights. In all purely scientific matters, in all reforms that are educational or sanitary, they really control public opinion. Their medical journals agitate the questions of reform, and discuss freely every measure that in any manner may concern them professionally. So much interest is taken in such matters by the medical men generally, that the opinions uttered by *The Lancet* (London), as the representative medical journal of the country, are so much respected even by laymen, that they are often quoted in parliamentary discussions, carrying with them an astonishing amount of weight and influence. It is for the very reason that the profession are so alive to their rights and interests that the authoritative ex-

pression of its opinions is so useful as a means to an end. The profession there has become by this means a power which politicians and wire-pullers prefer to conciliate rather than browbeat, and the least concession that can be made is the bestowal, as a matter of right, of all offices strictly medical. If their example be followed by us, the same results may be attained, and, as in their instance, must surely work for good.

The first step to be taken is to remove the conventional odium which attaches itself to the holding of political offices, and the manifestation of a reasonable interest in the success of such medical men as may from one motive or another consent to throw themselves upon our suffrages. There are certain public offices which should legitimately belong to the profession, and would be seized accordingly, were we to manifest less apathy in regard to the prospective incumbents. One of these offices is that of coroner. It is the exception rather than the rule that medical men ever hold them. To any one unacquainted with the amount of political corruption so rife in the metropolitan district, it would seem strange that any uneducated man should hold so high and important an office; but such is the fact. Instead of a properly qualified medical man as the incumbent, his rightful place is occupied generally by some political hack, who, per necessity alone, appoints a physician his deputy. These latter gentlemen are not only competent to attend to all the duties of their chiefs, but, in addition, perform the much more important ones of determining the causes of death. Under many circumstances the coroner, not being a medical man, may not only be a useless functionary, but an incumbrance to the ordinary course of justice. For instance, if any physician be arrested for supposed maltreatment of a case, the coroner, if he choose to act stubbornly by impanelling an ignorant jury, and refusing to acknowledge any peculiar circumstances connected with the alleged malpractice, may be the means of disgracing an innocent man, and procuring his lodgment in a State prison. There are cases of supposed maltreatment which, however apparent they may be as to intention of evil to ignorant jurymen, are perfectly clear to the contrary when submitted to the judgment of his peers. The requisite care in empanelling a jury of his peers in such cases is not often enough taken; but its necessity would be invariably appreciated by a medical man, if he were the principal with power, instead of a deputy without power.

When medical men have been coroners, we find them fully capable of performing their legal duties, while their strictly professional ones are absolutely indispensable. The same may be said with regard to the other offices which rightly belong to the profession, such, for instance, as those of Health Commissioners, Health Officers, Sanitary Inspectors, Registrars, etc., etc. In conclusion we reiterate the conviction that the proper performance of the functions that belong respectively to these offices, the physicians who may have been privileged to hold them have, as a rule, been more than ordnarily efficient, and have reflected credit upon their profession. The community have not been backward in appreciating such service, and if the profession had the courage to speak on its own behalf in the legislative halls and through the medical press, their endeavors to do good would be heartily indorsed. If we desire to obtain our rights and exercise our privileges, we must demand them on our own behalf before we can expect laymen and the community in general to become specially interested in the matter. We trust that opportunities may be granted in future for giving a practical turn to these remarks, by the course which the RECORD may take in speaking for these rights of the profession.

IN the present issue we have devoted a considerable space to the discussion on the Pathology of Tuberculosis before the Academy of Medicine, believing it to be a subject in which the profession at large are more than usually interested. As it is not yet completed we shall endeavor in future numbers to present the different views of several prominent members of this body.

Reviews and Notices of Books.

THE CELL DOCTRINE: Its History and Present State. For the Use of Students in Medicine and Dentistry. Also, a copious Bibliography of the subject. By JAMES TYSON, M.D., Lecturer on Microscopy in the University of Pennsylvania, and on Physiology in the Pennsylvania College of Dental Surgery; Fellow of the College of Physicians of Philadelphia, etc., etc. With a colored plate and other illustrations. Pp. 150. Philadelphia: Lindsay & Blakiston. 1870.

THIS manual is a useful and interesting digest of the views in former times and at present entertained by leading histologists in regard to the nature and functions of the ultimate structural element of all tissues; the so-called cell. The author traces the expansion of our knowledge historically, presenting in chronological order the names and opinions of the most famous contributors to this branch of science. His own views correspond closely with those of Prof. Beale. Schleiden and Schwann taught that of the four parts of the cell the nucleolus was the oldest, controlling the nucleus, which in turn determined the condition or behavior of the cell contents and cell wall. Modern histology reverses this order: showing that the cell wall is the oldest, and the nucleolus, when present, the youngest part of the structure.

Not the least important part of the book is the bibliographical list, which bears evidence of thoroughness in its compilation, and which will be of much service to any student of this subject.

The colored plate illustrates the theory of Beale, and is borrowed from his works. Certain other cuts, chiefly from Virchow, are intercalated with the text.

If we consider Dr. Tyson's book from an historical point of view alone, it will be found a very desirable addition to any medical library.

PHOTOGRAPHIC REVIEW OF MEDICINE AND SURGERY. A bi-monthly illustration of interesting cases, accompanied by notes. Edited by F. F. MAURY, M.D, and L. A. DUHRING, M D. No. 1, Vol. I., October, 1870. Published by J. B. Lippincott & Co., Philadelphia.

THE first number of this new journal contains four admirable photographs, illustrating multilocular hydatid tumor, meningocele, horny tumor, and keloid tumor. Each case is accompanied by descriptive notes and opinions, with some account of treatment and its results. The contributors to the present number are Prof. S. D. Gross, D. Hayes Agnew, W. M. Pancoast, and F. F. Maury. It is the intention of the authors to select only striking and characteristic cases for publication, and to present them in the highest style of photographic art. The general appearance of the journal is excellent, and it promises to become a valuable addition to medical literature, filling a new and important field.

THE PHYSICIAN'S PRESCRIPTION RECORD: Containing nearly Four Hundred Prescription Blanks, with Forms for Record of the Condition of the Patient and Copy of Prescription. Philadelphia: S. W. BUTLER, M.D. 1870. 12mo.

As its title indicates, this is little more than a blank book intended for the registry of the condition of the patient, etc. Each page is divided into three sections, the upper of which is arranged as a record of pulse, tongue, temperature, etc.; the middle section is the prescription blank, to be filled for the apothecary; while below is the copied prescription. The middle portion of the page only being torn out, the book is thus made to preserve its shape.

It is in some respects a copy of the Prescription and Clinic Record of Dr. E. Seguin of this city, being arranged on a somewhat different plan, which with some practitioners may give it a preference.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

STATED MEETING, OCT. 26, 1870.

DR. J. C. HUTCHISON, PRESIDENT, in the Chair.

(Continued from page 449.)

PECULIAR "PISTON SOUND" OF HEART, ETC.

DR. LOOMIS:—The specimens I have to present are the heart and lungs of a patient who died of pulmonary phthisis, on the 25th of the present month, in Bellevue Hospital. I present these specimens on account of the peculiar physical signs that existed some time previous to death. The patient was of African descent, 28 years of age, married, with no hereditary or acquired predisposition to disease,—had always been well, until a month before his admission into the hospital, at which time, after exposure, he began to cough, and suffered from pain in his chest. His sputa were mucopurulent from the first. He never had night sweats, but had exacerbations of fever in the evening,—lost flesh and strength rapidly, and suffered extremely from dyspnœa.

At the time of his admission he was greatly emaciated, and unable to get out of bed without assistance; at times delirious; had pain in his chest referable to præcordia; was easily agitated; tongue dry; pulse, 100; respirations, 40; temperature, 102.

On physical examination, inspection showed depression under both clavicles, most marked on the right side; chest expansion diminished equally on both sides, slight up and down movement in front; left scapula moves more than the right.

By palpation, vocal fremitus much increased in the right infra-clavicular region, and a peculiar thrill was communicated to the hand as it passed below the third rib. In the left infra-clavicular region, vocal fremitus was slightly increased; over the scapula it was also increased, but over the infra-scapular regions, on both sides, it was diminished.

On percussion, there was marked dulness over the right lung in front; there was slight dulness combined with extra resonance in spots over the same lung posteriorly. Extra resonance over the left lung behind and in front. Below the fourth rib in front, on the left side, the percussion note was tympanitic; this tympanitic resonance also extended over the area of normal præcordial dulness. The result of succussion was negative.

Auscultation revealed amphoric breathing, amphoric whisper and gurgles over the right lung anteriorly. Also a *peculiar sound, synchronous with the heart's action*, was heard all over the right side anteriorly; the point of maximum intensity of this sound was at the junction of the fourth rib with the sternum on the right side. It was a double, blowing sound, widely diffused in its area, and resembling that produced by the working of the piston-rod of a steam-engine; it was occasionally accompanied by a metallic click, which could be modified or removed by a change of position, or a cough.

On the left of the sternum, at the junction of the third costal cartilage, a slight systolic murmur was heard, transmitted upwards.

The apex beat of the heart was felt about 1½ inches inside of the right nipple, and on a line with it. The sounds, with the exception mentioned, seemed normal. There was also pulsation just below the ensiform cartilage.

Respiratory murmur over the right lung posteriorly was rude, and accompanied by large and small mucous râles. Over the left lung it was rude and exaggerated in front, and feeble behind.

The peculiar sound before mentioned, at times was so loud as to be heard several feet from the patient. It ceased entirely, at irregular intervals, for several minutes. During the interval the heart-sound could be distinctly heard.

On October 22d, at 10 A.M., the pulse was 130; respiration, 44; temperature, 101. *The piston-friction sound* already mentioned ceased this morning; occasionally it shows a tendency to return, ending either in a metallic click, or a single indistinct blow.

October 23d, the patient became wildly delirious. Pulse, 120; respiration, 44; temperature, 100; tongue brown and dry; subsultus. Patient gradually passed into a state of coma, and died at 3 P.M., October 25th.

Autopsy, twenty-four hours after death.—Brain and membranes normal, with the exception of slight pigmentation of the arachnoid in the vicinity of the vessels.

On the left side, the pleural cavity contains some air; the lung, however, was not compressed, and there was no evidence of inflammation of the pleura. The heart was found behind the sternum.

On the right side there was a small cavity, the size of an orange, situated partly in the upper and partly in the middle of the right lung. The walls of this cavity were formed on their inner or right side by lung tissue, and to a considerable extent by the inner surface of the pulmonary pleura, to which remnants of lung tissue were attached. The cavity contained air, and a little thick curdy material. A bronchus opened

into the upper part of the cavity. The cavity was situated directly over the pericardium.

In the upper lobe of the right lung there were small, cheesy pneumonias, and a cavity at its apex; throughout the whole lung there were points of fibrous induration; the bronchial tubes at many points were plugged up. In the lower lobe there were lobules of recent and cheesy pneumonia. Some of the bronchi contained pus, and others cheesy matter. At some points the walls of the tubes were also cheesy.

The left lung was congested and œdematous, with some spots, few in number, of recent pneumonias, having cheesy centres. In the upper lobe there were two spots of fibrous induration, of the granular form. The bronchi going to these spots were plugged up by cheesy and cretaceous matter. Other viscera were normal.

There were three views as to the mode of the production of this piston-friction sound: 1st, that it was a modified cardiac murmur; 2d, that it was a pleuro-pericardiac friction sound; 3d, that it was produced in the cavity or the lining by the rubbing of two surfaces of cavity together, or the forcing air out of cavity by the heart's action against the walls of the cavity.

Dr. Jacobi was inclined to think that the sound referred to was occasioned by the friction of the roughened outer wall of the cavity against the pleura.

Dr. Loomis did not think Dr. Jacobi's view was tenable, inasmuch as the walls of the cavity were very rigid in the first place, and that it was hardly supposable that the cavity could be so entirely empty at such times as the peculiar sound was heard.

Dr. Jacobi did not think that the entire emptying of the cavity was necessary.

Dr. Flint gave his explanation of the sound in the cavity thus: A tuberculous cavity was situated close to the right side of the heart, and, with the systolic and diastolic movements, rubbing of the roughened inner surface of the cavity took place. I have reported precisely such a case in the second edition of my work on the heart—under the heading Cardiac Pleural Friction Murmur. I supposed that case to be unique.

The Society then adjourned.

Stated Meeting, November 9, 1870.

Dr. J. C. Hutchison, President, in the Chair.

In the absence of the Secretary, Dr. R. E. Van Gieson was appointed Secretary "pro tem.," and made the following report:—

GASTRITIS CAUSED BY OVER-DOSE OF TR. VERATRUM VIRIDE.

Dr. Finnell presented a portion of the stomach removed from a lady sixty years of age. The mucous membrane was highly injected, showing evidence of intense gastritis.

The lady was attended by a homœopathist residing in Thirty-fourth street. He found her suffering from hepatic distress, accompanied by occasional vomiting of bilious matter. His prescription for this trouble was ten drops of Norwood's Tincture of veratrum viride, to be given once every three hours. The woman, though vomiting terribly after each dose, continued until six doses were all taken. After taking the sixth dose she sank and died from exhaustion. This is what is termed homœopathic treatment. The death was undoubtedly caused by the large doses of veratrum viride inducing fatal acute gastritis.

Dr. Finnell would like to inquire if any one would give the homœopathic dose of ten drops of veratrum viride for hepatic congestion.

Dr. Hutchison stated that within a month he had given half-drachm doses of Squibb's fluid extract of veratrum viride in a case of puerperal convulsions until three drachms in all were taken, and the woman recovered. He had every reason to believe that she recovered in consequence of taking this remedy. This result coincides with the experience of some of his medical friends who have also used this remedy in puerperal convulsions.

Dr. Finnell.—Five drops will, in the majority of cases, produce an alarming lowering of the pulse.

Dr. Hutchison had seen nearly fatal results with five drop doses, but in this case I advised the remedy in large doses, and the woman got well; whether it was a case of "*post hoc ergo propter hoc*" he could not say, but thought the recovery was due to the remedy.

UTERUS FROM CASE OF PUERPERAL CONVULSIONS.

The second specimen consists of a uterus and appendages taken from the body of a young woman aged eighteen years, who had arrived at the full term of pregnancy. She was confined in a most infamous den in Chatham street, No. 94, where poor unfortunates are taken in day by day to get rid of their troubles, and then sent away. This girl entered the place and remained three days, during which time she had puerperal convulsions, and died at the end of the third day. Dr. Finnell saw her shortly before she died: she was then moribund, and nothing in the way of treatment could be done. The uterus is apparently healthy. The walls are from one-half to three-quarters of an inch in thickness. There is no abrasion or laceration of the os. The death resulted from the convulsions alone, caused by uræmic poisoning, as the body was œdematous in the highest degree. Both ovaries show the beginning of ovarian cyst, and on the left side the Fallopian tube is involved.

The place where this unfortunate girl died is one of the lowest dens which New York City contains. Face to face in a room not larger than twelve by sixteen feet, large-bellied women were waiting for their turn to come next. What becomes of the children they do not know. In one instance the child had been choked a little while, and in that way was gotten rid of. It is said that the children are sent to the foundling hospital, but probably but few of them reach there. During the whole time of this girl's illness nothing whatever was done. It is reasonable to suppose that had she been properly treated she might have been saved.

Dr. Finnell, being one of the jury to try the Doctor of this establishment, would like to know if this woman was not grossly neglected, and whether a charge of criminal neglect and carelessness could not be brought in?

Dr. Hutchison. — There can be no two opinions with regard to that.

UNDISCOVERED FRACTURE OF SKULL.

Dr. Flint presented a brain with the following history from the Hospital records:—

Bellevue Hospital, Nov. 4, 1870.

Unknown man brought in by ambulance. Nothing known of his history; found insensible on the street. Age about 30, medium size, five feet five inches high; moderately nourished. The left side of the thorax diminished in size. Retracted approximation of the ribs. Marked lateral curvature of the spine, convexity towards right side; left side four inches smaller than right.

On admission, patient is in a comatose condition. Pulse 80, and full; temperature 101; skin moist, facies

dull, pupils slightly contracted and respondent. No external mark of injury. Scalp thoroughly examined, nothing found. Breath loaded with whiskey fumes. Respiration 24, and somewhat labored. Physical examination shows nothing, except a fine dry friction sound on the left side posteriorly. Urine normal, heart normal. Patient partially aroused with an effort and rolls about, throwing his hands up to his head until let alone, when he again becomes quiet. Evening—Pulse 76, still full; temperature 101. Somewhat more delirious than he was this morning; mutters incoherently. Nov. 5.—This morning is much wilder, has to be restrained in bed; temperature 101, pulse 72. Pupils somewhat dilated and respondent; respiration 30, but easy.

Died at 4.30 P.M., very delirious.

Autopsy Nov. 9. Some hemorrhage in tissue of the scalp. There is fracture of the skull, extending from left part of the lambdoidal suture, through the occipital bone to the jugular fossa. Firm clotted blood in the lateral sinus, near point of termination in jugular vein. Cavity of arachnoid on right side contains a large amount of clotted blood adherent to middle lobe of brain, extending from base half way up the convexity. The pia mater at this point is torn, and brain is lacerated. Laceration of anterior lobe at the base. Some blood in the meshes of the pia mater on the right side. Thickening of the pia mater on both sides, along longitudinal sinus, with numerous pacchionian bodies. The veins of pia mater in the left side are very much congested. Left lung firmly adherent to chest wall, lung compressed. Right lung normal, as also the liver, spleen, and kidneys.

DR. FLINT saw the patient not long after admission, and supposed from the odor of his breath, and the absence of certain other conditions occasioning coma, that the case was one of alcoholism. He was in doubt whether the increased temperature was in favor or against this diagnosis. The fracture has probably caused meningitis in the second stage, as there is a little lymph effused beneath the arachnoid. The interest of the case lies in the fact that a fracture of the skull existed, which after examination by the house surgeon was not discovered; and the practical lesson is, that we should examine the skull very carefully in cases of coma unattended with previous history.

DR. BIBBINS related a similar case, where the temporal bone was fractured, occurring in his own practice, and thought that it was an easy matter to overlook a cranial fracture. In this case the diagnosis was rendered more difficult from the fact that the intellect was unimpaired until shortly before death.

DR. FINNELL stated that such cases are not unfrequently revealed in coroners' examinations.

CANCEROUS TUMOR.

DR. VAN GIESON presented the stomach, liver, pancreas, and spleen, all taken from the same subject, and all more or less involved in carcinomatous disease. The specimen he considered chiefly interesting on account of the obscurity in diagnosis. He first saw the patient in the early part of October, and found as the main objective point of interest a large pulsatile tumor in the epigastric region. The enlargement seemed directly on the median line, extending downwards to the umbilicus, and on either side about two inches. The impulse was remarkably strong, and the unaided ear could easily detect a very loud and distinct systolic murmur. Lateral pulsation was also distinct. Tolerably firm pressure upon the tumor produced a feeling of nausea, but no pain. The patient's general condition at this time was anæmic and suggestive of the cancerous cachexia; but the physical signs seemed to point very strongly toward abdominal aneurism. During the whole of his illness the almost entire absence of pain was a noteworthy fact. At no time was it ever necessary to give an opiate to secure rest or freedom from pain. On the 12th of October a consultation was held with Dr. Ford of Brooklyn, the family physician, and the growth very thoroughly examined. At this time it was found that change in position modified the strength of the impulse, and diminished the distinctness of the murmur. The murmur and impulse, when the patient was made to sit up and lean forward, almost entirely disappeared; by grasping the tumor and lifting it forward, impulse and murmur seemed entirely gone. At this time the patient's stomach was extremely intolerant of food, but vomiting was not attended nor caused by pain. The vomiting appeared more like simple regurgitation. The evidence between carcinoma and aneurism at this time seemed pretty evenly balanced. The result of the consultation was in accordance with the evidence. Dr. Van Gieson was rather in favor of aneurism or omental cancer, while Dr. Ford felt certain of cancer of the stomach; both agreed in excluding the liver from forming a part of the tumor.

On the 23d instant Dr. Flint was called in consultation, and the patient again examined. During the interval the growth had enlarged considerably, and the impulse was somewhat stronger than before.

DR. FLINT in his examination elicited a new point in the diagnosis which previously had not been present, or else had escaped our notice, and that was *a distinct second murmur*. He gave as his opinion that the evidence derived from the physical signs strongly preponderated in favor of aneurism.

The patient survived until the 3d of November, and then sank quietly from asthenia. At the post-mortem examination, the left lobe of the liver was found considerably enlarged, and the seat of an abscess near the gall-bladder. At this point the stomach was adherent to the liver, and through the gastric walls was an opening about the size of a large penny, through which the contents of the abscess had partially escaped into the stomach. The stomach itself is the seat of very extensive carcinomatous deposit in all stages of degeneration, from the hardness of the initial change to the pultaceous softening and purulent discharge denoting complete disorganization. The right lobe of the liver is also enlarged, and the seat of scattered spots of secondary deposit. The abscess of the left lobe is evidently the direct result of the breaking down of a large nodule of cancerous deposit.

The spleen has upon its surface two patches looking somewhat like a cicatrix. The abdominal aorta was carefully examined, and found to be entirely free from disease or adhesions.

The points of interest in this case are, first, the almost total absence of pain during the whole course of the disease; and, second, the existence of a second murmur, which, perhaps more than anything else, led Dr. Flint, after a most patient and thorough examination of the patient, to think that the evidence in favor of aneurism preponderated.

DETACHED PLACENTA.

DR. VAN GIESON presented a second specimen, consisting of a placenta showing marks of detachment near the centre and lateral border, with the following history.

Mary M——, æt. 32, the mother of two healthy children, was taken in labor at full term shortly after midnight on the morning of the 7th of Novem-

ber, 1870. On the preceding afternoon she had taken a moderate walk. The pains did not act as usual, but their character was not accurately determined, except to learn that they were feeble, insufficient, and attended with a peculiar feeling of uneasiness at the epigastrium.

At about 2 A.M., her attending physician was called and found her with a pulse of 135 to the minute, blanched features, great thirst, and with but very feeble expulsive pains.

At this time the external hemorrhage was but slight, and yet it was evident that the woman was in an alarming state of collapse. The os was now rigid, and of a size barely permitting the finger to enter the womb. The membranes were tense.

A physician living near by was now called in, and after a short consultation hemorrhage from detached placenta was diagnosed, and the membranes ruptured as the first step in the treatment. Ergot, which had already been given, was now administered freely and frequently, together with occasional large doses (teaspoonful) of laudanum. Although the head now descended, and seemed to fit against the rigid fibres of the os so accurately that leakage would appear to be impossible, yet the bleeding still continued,—slight between the feeble pains, but with very abundant gushes at each expulsive effort.

The situation at this juncture was discouraging in the extreme. Both physicians were reasonably certain of the diagnosis, fully appreciated the impending danger, and were yet powerless on account of the non-dilatation of the os.

Unable to introduce the forceps without danger of rending the uterus, they still continued to give ergot and laudanum in heroic and frequent doses; meanwhile the os very slowly yielded, while the fundus seemed to have a little more contractile force during the pains. At about 6.30 A.M. I was sent for, and arrived at the bedside at 7.30 A.M., some five hours after the probable beginning of the labor.

The woman had now but feeble pulsation at the wrists, the eyes were turned back, the face blanched, —in a word, she seemed entirely exsanguinated. The os was now sufficiently dilated to admit the cautious introduction of instruments. The forceps were at once applied, and in a short time—certainly less than fifteen minutes—the woman was delivered. The bloodless child gave a gasp or two and died. The cord was broken near its middle. I think this occurred during delivery, although it is but fair to state that the attending physician, a most intelligent obstetrician, thinks the break in the cord may have been intra-uterine, and therefore a probable superadded cause of the hemorrhage and sudden death of the child.

The delivery of the child was followed by abundant dark clots of old blood. On introducing my hand in the uterus I found the placenta free. Its removal was followed by a chamberful of dark grumous blood, evidently some time effused. Energetic means were at once used to induce contraction. The hand kept in the cavity of the womb for this purpose could discover no rent or fissure in the uterine walls. The introduction of a large ball of ice was followed by feeble contractions. The ergot and laudanum were now resumed with the addition of ammonia, but in spite of all efforts the woman quickly expired at about eight A.M., some twenty-five minutes after delivery. I think with regard to the treatment, that with the indications gathered from this painful experience, I should not, in the future, place much dependence upon the use of ergot in such cases, but at the *earliest possible moment* would dilate and then turn or deliver with the forceps. A dose of ergot *just before* operating, to counteract the effects of suddenly unloading the uterus, would of course be useful, as it would tend to act at the close of the operation. Concerning the free use of ergot and laudanum after delivery there can hardly be but one opinion; but *first* and *foremost* in the treatment of this rapidly fatal complication I should most certainly place *manual interference*.

DR. FLINT stated that, in the examination of the first case, he felt quite certain that he heard, over and over again, *two* murmurs. He based his opinion of aneurism in a great measure upon the presence of the second murmur. The result has convinced him that hereafter he would be obliged to modify his opinion with regard to its significance as indicative of aneurismal tumors. With regard to the cause, it may be that the descending weight of the tumor produced a second wave of the vessel which gave rise to the murmur. He was not sure that this was philosophical, but he could think of no other mode of explanation.

DR. FINNELL stated that the puckered up appearance was not uncommon in all forms of peritoneal inflammation, and especially in cirrhosis. It was the result of fibrinous effusion.

With regard to the second specimen he referred to a similar case presented at the last meeting of the society, and in relation to treatment of the complication, said, that Dr. White at that meeting expressed himself as being in favor of ergot rather than totally and suddenly unloading the uterus, as this would be followed by complete inertia and still more alarming hemorrhage. Dr. Finnell thought from the fact that ergot was freely given in the case just presented, and yet with an unfavorable result, that in another case he would urge the thorough and free use of ergot, and then use means to unload the uterus.

DR. BIBBINS would state in regard to the first specimen of cancer that he presented a similar case to the Society some ten years ago, wherein he had made the diagnosis of aneurism. There was absence of pain, and very strong superior and lateral pulsation. Dr. Clark, in his remarks on the case at that time, said, "While cancer was painful in other parts of the body, that cancer of the pyloric orifice *without ulceration* was not attended with pain."

DR. ROGERS thought that in nearly all the cases presented to the Society the usual history has been, that absence of pain had deceived the diagnostician. He had no doubt it was from that experience that Dr. Clark's remarks were suggested.

With regard to the second specimen, he stated that the earliest case of intra-uterine hemorrhage which he had met occurred a little after the second month. The amount of blood lost in two bleedings was sufficient each time to fill a large "pot de chambre," and the woman recovered.

DR. FLINT thought the remarks upon pain in cancer would tend to leave an erroneous impression. He wished his testimony to be recorded, that pain is present in the great majority of cases as a rule, although he had met cases in which pain was not present.

DR. WHITHALL had seen two cases of cancer of stomach, and two of abdominal aneurism. Pain was present in one case of cancer, and present in both cases of aneurism, attended with local tenderness and pain in the lower extremities, which might be taken for rheumatism.

MONSTROSITY WITH CYSTIC TUMOR.

DR. BIBBINS presented a monstrosity delivered at full term, with the following remarks: Upon the lower part of the trunk of this child, proceeding from the junction of the right buttock with the sacrum and

lower part of the spinal column, is a very large cystic (?) tumor. The mother is a healthy Irishwoman, 32 years of age, who had previously borne three children, all healthy. While carrying this child she felt extremely anxious concerning her confinement, as her shape and sensations were peculiar. She is not aware that any deformity exists in her family. The father has had primary syphilis and chancres. She was taken in labor on Tuesday last, a week ago. When the doctor was called the sac of waters protruded, but it was impossible to make out the presentation without rupturing the membranes. She was then left for a time. On calling again in the evening, and endeavoring to make out the presentation, the membranes were ruptured and the pains ceased; but it was still impossible to discover the nature of the presenting part. On Thursday the pains returned, but not much progress had been made. On introducing the finger in the os a fleshy mass could be felt, but no bony resistance could be detected. At 2 A.M. some three physicians were sent for, none of whom came, until finally Dr. J. L. Camel, their former family physician, arrived at about 8 o'clock in the morning. Dr. Bibbins frankly stated to him that he was unable to make a diagnosis. After a consultation we both failed to make out the presenting part, until an attempt was made to turn the child. A large fluctuating mass was then discovered. On pressing this mass the head was found at the fundus, but we failed to secure the feet. The mass was then punctured, after which, with great difficulty one foot was found, and then the other. Nothing farther was done until the mass was freely incised, after which delivery was easily accomplished. The tumor before incision was probably six times the size of the fœtal head, though we have nothing left here but the sac, inside of which is another tumor apparently connected with the spine. The mother is doing perfectly well.

DR. HUTCHISON stated that within a few months he had seen a tumor in this region containing some two quarts of fluid; believing it was not spina bifida he punctured twice, and then injected iodine; soon after this the tumor reappeared, and not long after the child died of cholera infantum. Dr. Hutchison referred to Sir James Simpson's treatise upon this subject, where similar tumors are described and illustrated as occurring *outside* of the spinal column. Sir James calls them coccygeal tumors.

RECURRENT FIBRO-PLASTIC TUMOR.

DR. POST presented a tumor removed last week from a lady aged 59 years. It was situated about three inches above the upper margin of the mammary gland, being the third production in that region. In July, a year ago, he removed a similar tumor from this patient just above the mammary gland; in June following another, three inches above the cicatrix of the first one, and recently this growth, which proceeded from the cicatrix of the second operation. The tumor removed in June was examined by Dr. Lewis, and pronounced to be fibro-plastic. It is interesting from its remarkable tendency to be reproduced without apparently affecting the general health or contaminating the system.

ANEURISM OF ABDOMINAL AORTA.

DR. POST presented a second specimen taken from a young man 37 years of age, complaining of pain in the lower extremities regarded as rheumatic, and neuralgic pains in the abdomen. He examined carefully for aneurism, but could detect no pulsation. On Thursday last he died suddenly, and the doctor was requested to give a certificate, which he refused to do without making a post-mortem examination, although he had a strong suspicion that the case was one of abdominal aneurism, from the character of the pains and mode of death. It was learned at the house that he had suddenly been taken with excruciating pain, and a feeling as if something had given way, after which he lived some 12 hours, during which time he was not remarkably prostrated, but gradually sank and died.

On opening the abdomen an aneurism was discovered just below the diaphragm, and blood was found effused in large quantities in the lesser omentum. The superior mesenteric is given off from the tumor. About a year ago Dr. Post visited a patient in the same house who had also died suddenly. The aneurism in this case was found just above the bifurcation. There was no prominence forward, but the growth had enlarged backward, eroding the vertebræ nearly to the spinal canal. It was so deeply situated that neither auscultation nor palpation detected it during life.

DR. SAYRE suggested, that as the muscles were good conductors of sound, such an aneurism might be detected by applying the stethoscope posteriorly near the spine.

DR. POST stated, that he had not examined the patient in this manner. With regard to the pain of aneurism and cancer, he considered aneurism by far the more painful disease, especially when a plexus of nerves is involved, which is frequently the case. He had seen a case of axillary aneurism attended by the most intense pain; it was subsequently discovered that the axillary plexus of nerves was completely imbedded in the walls of the aneurism.

DR. FLINT gave the history of a case of aneurism of the thoracic aorta which took a backward course, and was not recognizable by the ordinary physical signs. The chief symptoms were localized pain, spasm of the glottis, and feeble respiratory murmur, more feeble on the left side than the right. The case proved fatal by hemorrhage from the trachea.

EPITHELIOMA OF LIP IN PATIENT AGED 21.

DR. SAYRE presented a specimen of epithelioma taken from the lower lip on the left side from a young man 21 years of age. It has been about 18 months in attaining its present size. Opposite the growth was a hole in the teeth caused by the use of a clay-pipe. He considered the specimen interesting on account of the youth of the patient.

TUMOR OF GLUTEAL REGION.

DR. SAYRE presented a second tumor, the nature of which he had not examined, removed from a patient presenting himself to his clinique at the Charity Hospital. The subject was 43 years of age, and had a large swelling on the right gluteal region some six inches in diameter, with a fluctuating feel in the middle. This growth began some two years ago. It has not increased materially for the last six months. The central portion was not reddened until about two months ago. The tumor was laid open by a free incision six inches in length, when about a quart of fluid escaped. At the bottom of the abscess at the junction of the sacrum and the ilium this growth was found. Fifteen years ago the patient suffered from syphilitic necrosis, and the present growth may be of the nature of an exostosis. Both specimens were referred to the microscopical committee, when the Society went into executive session.

NEW YORK MEDICAL JOURNAL ASSOCIATION.

STATED REUNION, OCT. 28, 1870.

DR. ALFRED UNDERHILL, VICE-PRESIDENT, in the Chair.

LOCAL MEDICATION OF RESPIRATORY TRACT.

DR. R. P. LINCOLN read a paper on *The Advances in the Means for the Treatment of the Respiratory Passages.* After a brief glance at the advantages of topical treatment, wherever applicable, as compared with general medication, and at the rapid extension of its range of application, due to the great improvements in physical diagnosis, and to such inventions as the laryngoscope, endoscope, etc., the doctor spoke more particularly of the local treatment of the respiratory apparatus. We should not think of treating a sore finger simply by a dose of medicine thrown into the stomach. Just as irrational is it to attempt the cure of an ulcer or inflammation of the nose or fauces, or even of the pulmonary mucous membrane, by the same means, when we have at command the means of reaching the affected part directly. We can now diagnosticate, with great accuracy, the seat and the character of any lesion, from the anterior nares to the pulmonary vesicles; and by means of fluids properly atomized we can apply directly to the affected surface any medicament we please. That the smaller bronchioles and the air-cells can be thus reached has been satisfactorily established; but to accomplish this it is necessary that the spray for inhalation be of the finest, and that it be supplied constantly and abundantly. It was doubtless from failure to appreciate, or inability to meet, these conditions that experiments with this method of treatment had, up to a recent period, so often come short of full success, and that the method itself had rather fallen into disuse. But with a clearer pathology, new remedies, and perfected apparatus, the subject has awakened renewed attention; and results are now attained which were before vainly sought for. In almost every disease of the respiratory tract medicated inhalations prove a powerful adjuvant, and in very many cases they constitute the only treatment necessary.

The speaker now gave a *résumé* of the history of inhalation, from the time of Hippocrates to the present. In its various forms of insufflation of powders, fumigations, and inhalation of vapors and gases, it had for centuries been more or less practised, with a varying degree of success. But it was not until 1845, apparently, that the first rude attempts were made to introduce medicated fluids into the lungs by impregnating the respired air with their *spray.* These attempts led to others, and soon spray-producers differing in form and principle began to multiply. These were followed in detail through their successive modifications by Auphan, Sales-Girons, Matthieu, Fournier, Schnitzler, Waldenburgh, Lewin, and others, to Bergson, who, in 1862, applied the principle, at once generally adopted, of causing the fluid to rise through the medicine-tube by the rarefaction produced by a transverse current of air sent across its capillary point, this current coming from the capillary point of a second tube fixed close to the first and at right angles to it, and atomizing the fluid as fast as it escapes. Convenience soon suggested making the medicine-tube parallel to the horizontal air-tube for the greater part of its length, leaving its point, however, perpendicular to that of the air-tube, and bending it again above the medicine-glass so that it should dip vertically downwards into the fluid.

In 1866, Maus combined the suction power of Bergson's transverse air-current with the pressure of condensed air upon the surface of the liquid in the medicine-vial, in an apparatus the same in principle with that since become so famous as Richardson's atomizer.

In 1864 Siegle invented his steam atomizer, essentially the same as those now in common use.

We have no space here to follow the speaker through his account of these various nebulizers, but would refer the reader to figures and descriptions of the more important of them in MEDICAL RECORD, vol. i., pp. 169, 194, 219, 243; vol. iv., p. 328; vol. v., p. 237.

Dr. Henry K. Oliver, of Boston, introduced a valuable improvement in the mode of administration of atomized fluids. He had the spray produced inside a glass vessel, of about three pints' capacity, having one opening for the patient's mouth, and another for the admission of air and the escape of superfluous spray. This served not only to protect the face, but also—a most important point—to insure greater constancy and uniformity in the spray supply.

"In 1861, Dr. Sass, who had already spent much time and thought, and made many experiments, with the object of perfecting this means of treatment, conceived the idea of having the patient inhale directly from a reservoir so large that it would not be exhausted during the act of inspiration, and with a supply so ample and constant that the spray consumed by one inspiration would be more than replaced during the interval of expiration. To produce the atomization he employed an apparatus which he had used since 1848, and which was almost identical with that now known as Richardson's Spray Producer." It consisted of two tubes, one within the other; the inner tube (for the fluid) dipping nearly to the bottom of the fluid in the medicine-vial, and its other extremity terminating in a capillary orifice; the outer tube (for the compressed air) extending only through the cork of the vial, so as to communicate with the air-space above the fluid and force this up through the inner tube, and terminating at its other extremity in a capillary orifice just beyond that of the tube enclosed. "To generate his power, condensed air, he used a common air-pump. The reservoir for the spray was a cylinder of glass, three feet high and thirty inches in diameter, with four trumpet-shaped mouth-pieces in its sides, which could be introduced to different depths within the cylinder, for the purpose of reaching spray of different degrees of fineness." The patient inspires by the mouth and expires by the nostrils.

"The effect in treating patients, and the results of experiments on animals, proved that the object sought was more perfectly realized than by any arrangement before employed." But the cumbrousness of the reservoir, and the difficulty of cleansing it, led to "modifications in its shape, till, in 1863, it had been transformed through many stages to the shape we now use, and which you see before you this evening. Globular in form, it is open at one end, where the atomized fluid enters as it is formed, while the opposite end is drawn out into a shape to be easily held in the mouth. It is supported upon an arm that can be adjusted to any height convenient to the patient. Several reservoirs can be mounted upon the same stand, as in the instrument before you, thus avoiding an admixture of medicines, and affording the opportunity of administering inhalation to several patients at once. Should it be deemed advisable at any time to give the inhalation warm, this can be secured by placing a lamp under the medicine-glass, or by putting hot water in the reservoir itself. So important an auxiliary do we

consider this reservoir that we invariably recommend the addition of one to the common steam-atomizers, when these are to be used." In 1863 Dr. Sass had adopted the Bergson glass tubes for nebulizing, with the now common device of bending their extremities at various angles, so as to direct the spray towards the larynx, the posterior nares, etc.*

The special advantages claimed for the apparatus above described were: 1. The *fineness of the spray* produced—secured by using strong tubes with very fine orifices and a great pressure of air (thirty or more pounds to the square inch). "The finer the spray, the more thoroughly can the atmosphere be loaded with it, and the more readily will it traverse the ultimate ramifications of the air-passages." 2. By *inhalation from a reservoir*, kept fully supplied, the spray, instead of being driven against the sides of the mouth and pharynx, and being in great part precipitated there, or exciting spasmodic cough, so as to prevent its passing the glottis, simply saturates all the air respired, and must go wherever that can penetrate. 3. *Ability to regulate the strength of the spray inhaled*, the lack of which constitutes so serious an objection to the common steam atomizers.

The speaker concluded by a brief reference to other instruments devised by Dr. Sass, to be more fully explained by their inventor—an illuminator for the laryngoscope, endoscope, etc.; an improved endoscope; a tongue-depresser with curve to fit the tongue; a douche for the posterior and one for the anterior nares; a glass face-shield for use in applications to the nostrils, and others.

Dr. L. F. Sass exhibited his instruments and showed their operation. They were noticeable as well for their beauty and perfection of finish as for their evident practical convenience and utility. Besides those mentioned by Dr. Lincoln, there were displayed various surgical instruments for operations on the larynx, etc. We noticed also two convenient little inventions of Dr. Norton Folsom, one a wire speculum for the nostril, the other an appliance of hard rubber to be attached to the spray-tube or the laryngoscope-handle, for either drawing forward or pushing backward the velum.

Dr. Bumstead had been so much pleased with Dr. Sass's illuminator, which uses a gas flame, that he had had one made on the same pattern. It left nothing to be desired. The addition of a jet of oxygen thrown into the middle of the flame, which he had at one time tried, gave a light stronger than necessary, and he had returned Dr. Sass's own form as perfectly satisfactory. The endoscope, to which Dr. S. had added a magnifying combination of lenses, worked admirably; and, with the illumination just mentioned, No. 1 Jaeger could be read as easily as with the naked eye by daylight.

Dr. Farnham had had the pleasure of using one of Dr. Sass's spray-producers for a number of years, and it had taught him how imperfect and comparatively inefficient were those he had before employed. By its means a four hundred and eighty grain solution of nitrate of silver could be used with perfect safety—in cauterizing the vocal cords, for example. Its action was instantaneous, and perfectly under the control of the thumb. Such an application did not suffocate the patient—indeed, was hardly painful at the time—although there was afterwards a burning sensation for some hours. For the cure of catarrh, the speaker had employed the instrument with great success, after other means had failed.

* [The necessity for having several sets of tubes for this purpose is obviated by Dr. Burrall's simple contrivance of introducing a piece of flexible rubber tubing between the spray-tube and the medicine-glass. See Med. Record, vol. iv., p. 328.—Reporter.]

Dr. A. L. Carroll remarked that atomization was, perhaps, first employed in this country some dozen years ago by Dr. Dewees; and, as the Doctor was present, he would like to hear from him.

Dr. Dewees said that he was experimenting upon the subject at the same time with Sales-Girons, each being wholly ignorant of the other's work. He had devised a double-tube instrument attached to an air-pump; but it acted imperfectly. Soon after this, some of the better inventions were published, and he abandoned his own. He claimed only to have been one of the first, if not the first, to apply the spray in this country.

Dr. A. H. Smith remarked that for those who had no air-pump, a cheap and convenient motive power for the spray-producer might be readily found in the cylinders of oxygen, under a pressure of 250 pounds to the inch, as supplied by the Oxygen Gas Company. The pressure could be perfectly graduated by means of the cock.

He had made some experiments in illumination by the aid of oxygen without the addition of the lime-point. By slightly enlarging the holes of an Argand burner, and then throwing a jet of oxygen into the middle of the flame, he had obtained a strong white light with little increase of heat. A beautiful modification of this arrangement had been made by Dr. Piffard.

In the application of spray for cauterizing purposes, he had found the spray-tube itself hold enough fluid by capillary attraction; the medicine-vial might therefore be dispensed with, and then the same tube would serve to throw the jet upwards, downwards, or sideways. A second tube would be required, however, to throw it directly forwards.

Dr. Piffard remarked that, to furnish a motive power for the nebulizer, the cylinders mentioned by Dr. Smith could be more cheaply filled with condensed air than with oxygen.

Dr. Beard had found the application of a two or three grain solution of nitrate of silver, by means of the posterior nasal syringe, cause great pain. He was convinced that a solution of this strength was more painful than a four hundred and eighty grain solution.

To obviate the danger attendant upon the use of Thudicum's nasal douche, the apparatus had been modified by attaching to it a tube for the free outflow of the fluid.

The speaker wished that an apparatus so valuable as that exhibited might be brought within the means of physicians in general practice, and hoped Dr. Sass would exercise his ingenuity to simplify it to this end. Not one out of a hundred of country patients suffering from catarrh could come to the city for treatment. There was the same difficulty with electro-therapeutics.

Dr. Pomeroy heartily concurred in the last remarks. Yet many of the most important purposes might be subserved by a slight modification of an instrument in every doctor's office. For a couple of years back he had depended, for cleansing the nasal passages, wholly upon a Davidson's syringe, to which he had attached, for the posterior nares, a hard-rubber nozzle, bulb-shaped, perforated with numerous holes, and bent so as to be easily passed up behind the velum. For the anterior nares he had a plain nozzle adapted to the shape and size of the nostril. With the Davidson you could inject your warm salt and water as gently as you pleased, or forcibly enough to remove the tenaciously clinging secretions. It was thoroughly effective in cleansing the naso-pharyngeal space, and it was certainly cheap.

Of spray-producers he had found one at Otto & Reynders' having the spray-tube made of hard rubber, and arranged with a swivel, so as to turn in any direction. The inner tube was of metal, which was objectionable; but he had had this replaced by one of hard rubber, and had the whole instrument made smaller, so as to pass the uvula without difficulty. For applying a solution of, for instance, nitrate of silver to the anterior nares, it was well to have a bulb behind the point of the spray-tube to fit the nostril, and so prevent staining. By having a hole in the rubber ball, to be stopped by the thumb, you could instantly check the production of the spray. With this simple apparatus you could apply a caustic solution behind the palate almost as quickly as you could turn up the eyelid and touch it with the sulphate-of-copper crayon.

DR. BURRALL could endorse the commendations of the apparatus exhibited. He had found his own illuminator, presented before the Association about three years ago, give sufficient light for very thorough laryngoscopic examination; and it was comparatively cheap. An excellent cylinder for holding condensed gases—small and portable, and capable of sustaining great pressure—was made by Grüber of this city.

DR. HOLCOMBE referred to a case of inflammation of the middle ear, which, according to the patient's statement, "had been punched up there by some throat-doctor who had injected a spray into his throat."

DR. DEWEES.—Some twenty-five years ago I was censured by Dr. Mott, the elder, who said I should probably cause the death of some patient by throwing injections through the Eustachian tube. I used to throw in a thirty or forty grain solution of nitrate of silver into the Eustachian tube, and I had also an exhauster by which I drew out often considerable mucus. I never had an accident in my practice, which was then quite extensive in ear-diseases; and I do not believe there is the danger that is supposed. The only danger seemed to be from the violence of the irruption of air into the tube, and this I was careful to avoid.

OZONE FOR INHALATION.

DR. DEWEES presented the apparatus, of which he had spoken at the meeting of October 7th (MED. RECORD, vol. v., p. 404), with the following remarks:

Many years ago I attempted to perfect an instrument by which oxygen could be inhaled. It failed most signally in practice, on account of the difficulty of getting pure oxygen gas. It produced much irritation. Now pure oxygen is readily and cheaply obtained. About two years ago I experimented upon the application of ozone. Knowing little about the subject, my work went lazily along, until, about five months ago, I proposed to my friend, Dr. Wilkinson, that he should get up an apparatus for the generation of the gas for inhalation; and this machine is the result of his ingenuity entirely. It consists of a Ruhmkorff coil, whose poles are connected with the metallic caps of a glass tube about two feet long by an inch in diameter, around the inside of which runs spirally a lightning-chain of platinum discs. To the brass cap at one end of the tube a mouth-piece for inhalation is attached; through that at the other end either oxygen or common air is admitted. The coil, which contains some five miles of wire, is animated by a two-cell battery, and will send a spark nearly two inches through dry air. When the connections are made the oxygen of the air in the tube is rapidly ozonized by the numberless sparks—so rapidly that by simply drawing the breath (of air or oxygen) through the tube you get a decided effect from the ozone produced. By modifying the strength of the battery and the length of the lightning chain, the amount of ozone generated may be increased or diminished.

I present this apparatus for use in pulmonary diseases, as enabling us to give the equivalent of a sound lung to a patient with the lung partially disabled. Oxygen, as it is taken into the system through the lungs, has probably to undergo this change into the active condition of ozone before it becomes efficient. It is thought by Dr. Wilkinson that very likely, this change of the oxygen of the air inspired is normally produced by the nerve-power. At all events, in typhoid conditions, where nerve-power is exceedingly low, we have very little oxidation going on. You might suppose that the ozone, by its chemical action, would irritate the mucous membrane of the respiratory tract, but it does not. This apparatus simply enables us to give active oxygen—to get the same effect as from a drive in the park or in the country, without the fatigue. By its means you can certainly give a patient, whose lung-surface for respiration is lessened by one-third or more, the full equivalent of the loss.

DR. WILKINSON now exhibited the apparatus in action, and its effects were tested by several members.

The meeting then adjourned.

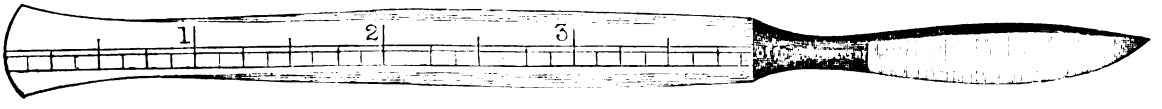
Correspondence.

A SYSTEM OF MEASUREMENT FOR MEDICAL STUDENTS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR—While brushing up my Surgical Anatomy last winter, I greatly felt the want of some handy means of verifying the numerous measurements of length, breadth, and relative distance given in the text-books. I therefore have devised a way of accomplishing this object, which I beg leave, through your journal, to place before the medical student. It consists simply in having a four-inch scale ruled upon the handle of a scalpel, as shown in the cut. By use of this device the student learns to become a close observer. At the same time the eye becoming trained to estimate distances correctly, the hand soon acquires that precision of movement so necessary in performing certain operations.

The opposite side of the handle is ruled in millimeters, after the French system—a secondary advantage, which I find of great convenience as a standard of reference.



Messrs. Otto & Reynders, of 64 Chatham Street, N. Y., are now prepared to furnish dissecting cases with these scalpels, at a trifling additional cost.

Very respectfully,

JOHN HOWE, M.D.

311 W. SEVENTEENTH ST., N. Y.,
November 12th, 1870.

ARMY AND NAVY NEWS.

List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from November 18th, 1870, to December 3d, 1870, inclusive.

MAGRUDER, D. L., Surgeon.—By S. O. 224, c.s. Headquarters Department of the Missouri, granted leave of absence for thirty days.

COWDRAY, S. G., Assistant-Surgeon.—By S. O. 221, Headquarters Department of the Missouri, November 22d, 1870: to proceed to Fort Gibson, C. N., and report to the commanding officer of that post for duty.

Medical Items and News.

BUREAU OF SANITARY INSPECTION—HEALTH DEPARTMENT,
301 *Mott Street, New York,*
December 7, 1870.

To the Board of Health Department,
EMMONS CLARK, *Secretary:*

I have the honor to submit the following statement of contagious diseases reported to this Bureau for two weeks ending Dec. 3d, 1870:—

Week Ending	FEVERS.			Small-pox.	Scarlatina.	Measles.	Diphtheria.
	Typhus.	Typhoid	Relapsing.				
Oct. 26.	6	53	5	2	55	39	5
Dec. 3.	4	45	7	2	61	43	7

Scarlatina having become epidemic throughout the city, I have given specific directions to the Health Inspectors to visit each case reported, for the purpose of instructing those in charge particularly as to the sanitary necessities in each case, giving directions how and what to apply as means of disinfection, and the sanitary care of all infected articles about or in the sick room.

For this purpose I have prepared a code of Rules which are to guide them in these efforts, and I desire to have them printed on small slips, for general distribution among those dwellings where this disease prevails, to wit:—

Scarlatina.—Every case of this disease must be reported to the Bureau of Sanitary Inspection on its first appearance.

Care of Patient.—The patient should be placed in a separate room, and no person allowed to enter the sick room except the nurse and the physician in attendance, or to touch the clothing or bedding used in the sick room, until it has been thoroughly disinfected.

Infected Things.—All clothing, bedding, and other articles not absolutely necessary for the use of the patient, should be removed from the sick room. Articles used about the patient, such as sheets, pillow-cases, or clothes, must not be removed from the sick room until they have been disinfected by placing them in a tub, with the following disinfecting solution: 8 ounces sulphate of zinc, 1 ounce carbolic acid, 3 gallons water.

They should be soaked in this fluid for one hour; and then be thrown into boiling water and thoroughly washed. Feather and hair pillows and mattresses require fumigation, and should not be removed from the sick room until after this has been done by the Disinfecting Corps of this Department.

Whenever the patient is removed from the sick room notification should be sent to this Bureau.

All vessels used to receive the discharges of patients should have some of the above solution kept constantly in them, and immediately after their use be removed from the sick room and emptied.

Water-closets and privies must also be disinfected daily with some of the same solution. A piece of muslin one foot square should be dipped in this solution and suspended in some part of the room constantly, and the same be kept in the hallways adjacent to the sick room. All straw beds should be burned after use, but should not be removed from the room except by permission of this Department.

It is advised not to use handkerchiefs about the patient, but rather old, soft rags, which should be immediately burned after use.

The ceilings and sidewalls of the sick room should be thoroughly cleansed and lime-washed whenever the patient has been removed therefrom.

Respectfully submitted.

Your ob't serv't,
MOREAU MORRIS, M.D.

NEW YORK SOCIETY FOR THE RELIEF OF WIDOWS AND ORPHANS OF MEDICAL MEN.—The twenty-eighth anniversary dinner of this benevolent society took place at Delmonico's, Tuesday evening, Nov. 29th, 1870. Abuut two hundred guests were present. The dinner, in every respect, was the most successful and elegant ever given by the Society. And in a pecuniary point of view it was all that the managers desired, as nearly $800 were paid into the treasury on that occasion. Twenty-three new members were also added to its roll of membership.

The Treasurer's report exhibited the following sums belonging to the Society, and invested thus:—

Bonds and mortgages	$36,500
United States 81s, coupon	1,000
United States 81s, registered	19,000
United States 5-20s registered	26,000
Total	$82,500

Subsequently to the disposition of the dinner. Dr. Oliver White, the President, delivered an appropriate and interesting address. He remarked that there was a gentleman present, Dr. Edward Delafield, through whose instrumentality the Society has been established, and it was at one of these dinners that the suggestion was first made which led subsequently to the establishment of the New York Academy of Medicine. He was gratified to say that there was not an original member of this Association who had ever turned back from the good work. This was a noble charity, which was worthy the attention of all medical men, and he hoped that it would prosper in the future as it had in the past.

The next speech was by Ex-Judge Edwards Pierrepont, who responded to the sentiment, "The United States of America."

Chancellor Crosby responded for the "Learned Professions: Divinity, Law, and Medicine." He was followed by Ex-Judge Clerke; Prof. Austin Flint, Senr., M.D.; Dr. John Moore, U. S. Army; Dr. Henry S. Wells, U. S. Navy; Charlton T. Lewis, Esq., who made a telling speech, in response to the toast, "The Press;" and Prof. E. R. Peaslee, M.D., who responded for "Woman."

Dr. W. Detmold, in a few happy and appropriate remarks, presented to the Society an expensive painting, executed by Hart, of Prof. Edward Delafield, M.D., its first President. This was ordered and paid for by a few members.

The members of the Society now number one hundred and forty-eight, including the twenty-three new mem-

bers. Aid is now given to six widows and three children of its deceased members.

Annual members pay an initiation fee of ten dollars, and ten dollars dues, in semi-annual payments; or one hundred dollars paid at one time constitutes a member for life. By the payment of one hundred and fifty dollars, or upward, one is constituted a benefactor.

Its efficient officers are as follows:—*President*—Oliver White, M.D.; *Vice-Presidents*—E. L. Beadle, M.D., J. O. Stone, M.D., S. Conant Foster, M.D.; *Secretary*—Jas. L. Banks, M.D.; *Treasurer*—J. W. G. Clements, M.D.; *Chairman of the Committee of Arrangements*—Alfred Underhill, M.D.

New York Academy of Medicine.—At the meeting held Nov. 3, 1870, Drs. James G. Clarke of New Brighton, Staten Island, and W. H. B. Post were elected Resident Fellows.

American Medical Association.—Members can obtain their copies of the Transactions for 1870, from Dr. A. E. M. Purdy, 123 East 38th st.

The Newly-Discovered "Durkee Spring."—The newly-discovered mineral spring at Portago, nine miles from Kalamazoo, Kalamazoo County, Michigan, called the "Durkee Spring," closely resembles in its nature and composition that noted one of "Spa," in Belgium. The *external* application of the water seems to be decidedly sedative, and is recommended in cases of rheumatic affections.

New York Academy of Medicine.—Of the thirteen Fellows who have been elected to preside over this Society, nine have been removed by death, viz.: Stearns, Francis, Mott, Stevens, Cock, Jos. M. Smith, Batchelder, and Watson. The average age of these departed Presidents, at the time of their decease, was seventy-five years; excluding Watson, who died prematurely of malignant disease in his fifty-ninth year, the average age was seventy-eight years.—*Dr. Gouvr. M. Smith's Discourse.*

The Massachusetts Medical Society.—At the stated meeting of the councillors of this society, held in Boston October 5th, Dr. Asa T. Newhall, of Lynn, was expelled for alleged criminal abortion.

The committee appointed by the councillors to take action on the report of the delegates to the American Medical Association presented several resolutions, which condemned the action of the American Medical Association in imposing conditions upon the rights of this society, which are deemed ill-considered and unwarranted. All of the resolutions were passed. The fourth resolution reads as follows: "The committee recommend that no delegates from the Society be sent to the next annual meeting of the American Medical Association."

India Ipecacuanha.—There has been a good report made of the progress of ipecacuanha culture in India, where it is found so valuable in that prevalent disease, dysentery.

Death of a Noted Author.—Fitzhugh Ludlow, author of "The Hasheesh Eater" and "The Opium Habit," recently died at Geneva, Switzerland.

Roman Life.—On consulting the tables of Ulpianius, founded on observations of one thousand years, we find that the mean term of Roman life was thirty years. At the commencement of the Christian era, this was the average length of life.

Cerebro-Spinal Meningitis in Providence, R. I.—Dr. Stephen S. Keene, Providence, R. I. (*Boston Medical and Surgical Journal*), records four cases of cerebro-spinal meningitis which occurred in the month of March, April, May, and July, in a dwelling-house occupied by one family, and were afterwards transported to the Rhode Island Hospital for treatment. These patients recovered from the acute attack, but suffered from the sequelæ, or the disease in its chronic form.

These were the only cases observed in Providence at that time or subsequently. Poison being suspected, careful chemical examination was made of the water and water-pipes without result.

So far as he has been able to ascertain, this is the first time that cerebro-spinal meningitis has been observed in Providence. The first and only record of its appearance in Rhode Island was in 1863, when it prevailed in the Naval School at Newport.

Death from Chloroform.—Recently, a female patient was placed on the operating table of the Cincinnati Hospital, for amputation of the foot, by Dr. Dawson. A small quantity of chloroform only was used, and the patient expired almost immediately after the completion of the operation. Fatty degeneration of the heart was revealed at the post-mortem examination.

Brigham Hall Insane Hospital, N. Y.—Since the opening of this Hospital, in 1855, 696 patients have been received; 219 have been discharged recovered; 137 improved; 151 unimproved; and 62 have died. 64 inebriates have been treated and discharged, with good results in many instances.

At the close of 1868, there were remaining under treatment 10 recent cases, and 34 were admitted in 1869, making the total number of recent cases treated in the course of the year 44. Of this number 30 were discharged recovered; 2 left improved; 2 unimproved; 2 died, and 8 remained at the close of the year 1869.

The Resident Physician, Dr. George Cook, hazards nothing in saying, that no array of facts or opinions could be more conclusive of the importance of early treatment in mental diseases, than the simple statement here made.

A Double-Headed Child.—Mrs. Finley, the wife of a respectable well-to-do farmer, of Morrow County, Ohio (*Cin. Med. Repertory*), was delivered, October 12th, of a living remarkable monstrosity, in the form of a *double child.* Each child has a separate stomach, but bowels in common.

The Turkish Bath in Lunatic Asylums.—The first lunatic asylum that introduced the Turkish bath was that in Cork, the largest, except one, in Ireland, with accommodations for five hundred patients. Since the introduction the cures have been 40 per cent.; before its introduction only 20 per cent.

The Inventor of the Mercurial Barometer.—The mercurial barometer was invented by Torricelli; he died soon after, in 1647, in his thirty-ninth year.

Original Lectures.

ON THE EFFECT OF INHALATIONS OF OXYGEN UPON THE PULSE.

Remarks before the New York Medical Journal Association, November 4, 1870.

By ANDREW H. SMITH, M.D.,

LECTURER ON MATERIA MEDICA AND THERAPEUTICS AT WOMEN'S MEDICAL COLLEGE OF NEW YORK INFIRMARY.

Mr. President—Observations which I have recently made upon the pulse, as affected by the inhalation of oxygen, tend toward fixing some points heretofore undetermined.

The first series of observations, one hundred and two in number, were made upon eleven phthisical patients. In seventy-two of these observations the pulse was retarded an average of ten beats per minute; in eighteen its frequency remained unchanged, and in twelve there was an acceleration averaging six beats per minute.

The average frequency of the pulse in the observations showing a decline was ninety-six; in those in which there was no change, ninety-seven; and in those in which there was a rise in the pulse, ninety-four.

These figures correspond so closely that their difference does not afford any explanation of the results obtained.

Of the eleven patients, three uniformly exhibited a fall of the pulse. In the remaining eight the result differed in different observations, the pulse sometimes remaining the same, sometimes rising, but more frequently falling; each individual conforming closely, on the whole, to the average already given.

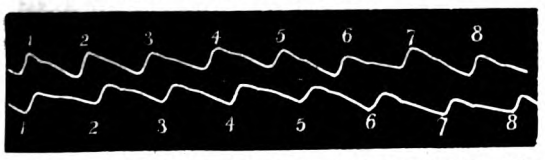
The second series, consisting of twelve observations, were made upon twelve persons in health.

Of these, in four there was no change, in the remaining eight there was a fall, averaging nine beats per minute.

If the reduction of the pulse had been confined to the *phthisical* cases, where the range was upwards of ninety, and in some cases above one hundred, we might suppose that oxygen acted only as a stimulant, and produced merely the effect which brandy might have caused. But in view of its action upon the pulse in *health* this explanation is not tenable. So far as these experiments go they seem to indicate that oxygen is an arterial, or, more correctly, a cardiac sedative.

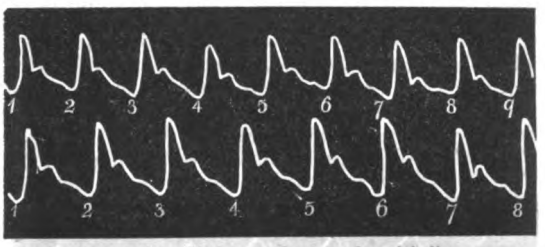
It does not follow, however, that the mode of action is analogous to that of digitalis or veratrum viride. It is more probable that the result is brought about indirectly, the first step being a change in the blood which facilitates its circulation and thus lessens the labor imposed upon the heart.

A third series of fifteen observations were made by the aid of the sphygmograph upon ten persons in health and five suffering from disease. In two cases no change whatever was observed, and in two others there was simply reduced frequency, as shown in tracing No. 1.* In the remaining eleven there was more or less change in the *character* of the beat. In studying these changes it is necessary to bear in mind that the volume of the pulse is influenced by four conditions: 1st, the force of the cardiac systole; 2d, the aggregate quantity of blood circulating; 3d, the condition of the artery; and 4th, the resistance which the blood meets with in its circulation. As, however, the quantity of blood and the condition of the artery could not change in the short time required for these observations, the problem is narrowed down to considering the effect upon the heart's action and upon the resistance to the circulation.



No. 1.—Simple retardation without change of character, from inhaling oxygen.

Now, as we have seen that in about 70 per cent. of the first and second series of observations the heart's action was very considerably retarded by the oxygen, thus giving more time between the contractions for the ventricle to become filled with blood, we should naturally expect that the systole, throwing an increased amount of blood into the arteries, would occasion an increased volume of the pulse. The sphygmograph shows that this effect actually results in a considerable proportion of cases, as is well shown in



No. 2.—Retardation with increased volume from inhaling oxygen.

the tracings marked No. 2, which I will now pass round. But in other cases, with reduced frequency of the pulse, the volume remains the same, or is even diminished. Does, then, the sedative effect of the oxygen, in these cases, extend to the *force* as well as the frequency of the cardiac contractions? I think not. Clinical observation goes to prove that oxygen is a tonic, giving tone and vigor to the muscles and to the system generally, an effect totally at variance with the idea that it debilitates the heart. The true explanation, as I conceive, is to be found in the effect of oxygen upon the capillary circulation.

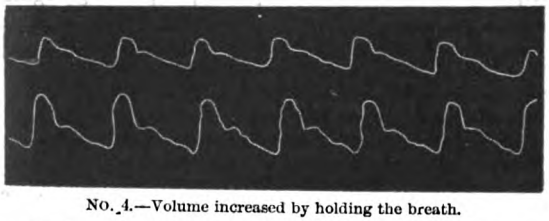
It is clear that the volume of the pulse must be greatly influenced by the resistance which the blood meets with in passing through the capillaries. If obstructed in its flow an increased distension of the artery

No. 3.—Volume increased by obstructing the veins of the arm.

from the *vis a tergo* must result. This is shown by tracings No. 3, the first line of which represents the natural pulse, while the second shows the effect of obstructing the venous circulation by placing a ligature above the elbow, as for venesection. You will observe that the volume is more than doubled. That the same effect may be produced by influences operating upon the blood itself, is shown by No. 4, in which the volume of the pulse is enormously increased by simply holding the breath. Either the fluidity of the blood is lessened

* The cuts represent a transit of 5⅕ seconds.

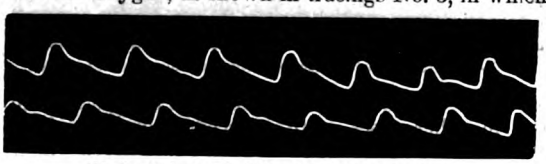
by imperfect arterialization, or the vital attraction which is supposed to facilitate the capillary circulation is diminished. At all events, the passage of the blood is retarded.



No. 4.—Volume increased by holding the breath.

Such being the effect of *increasing* the capillary resistance, it is not unfair to assume that a contrary result would follow if this resistance were *diminished*, and we should therefore expect to find that when the passage of the blood through the capillaries was in any way facilitated, the volume of the pulse would be, *cæteris paribus*, diminished. And since a deficiency of oxygen in the blood obstructs the capillary circulation, it is reasonable to suppose, though it does not necessarily follow, that an excess of the same agent would facilitate it, and thus tend to neutralize the effect upon the pulse of an increased volume of blood thrown into the arteries by the cardiac systole. This explanation accords with the effect of oxygen upon the dicrotism of the pulse, as we shall presently see.

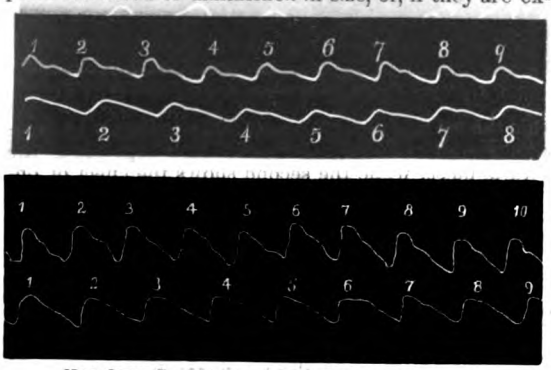
An extension of this principle will account for the effect of oxygen, as shown in tracings No. 5, in which



No. 5.—Volume diminished by inhaling oxygen.

it greatly reduces the volume of the pulse. These tracings were taken from a *bon-vivant*, very plethoric, with congested capillaries and a tense, full pulse. We can easily conceive that in such a case anything which would aid the passage of the blood through the capillaries would lessen the distension of the artery from the cardiac impulse.

My view then is, that oxygen acts at the same time upon the heart, to reduce the frequency of its contractions and increase the quantity of blood thrown out at each systole, and upon the blood, to facilitate its flow through the capillaries; that these actions are antagonistic in their effect upon the volume of the pulse, and that, as one or other predominates, we shall have the pulse increased or diminished in size, or, if they are exactly apportioned to each other, that there will be no change of volume.

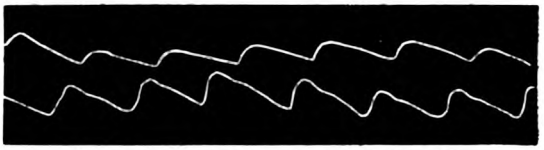


Nos. 6 and 7.—Dicrotism removed by inhaling oxygen.

The effect of oxygen upon the dicrotism of the pulse depends, I believe, upon the same principles. Dicrotism being the result of a reflux wave rebounding from the obstruction encountered in the capillaries, it will be diminished in proportion as the obstruction is lessened.

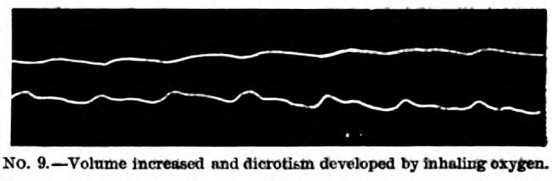
This is well shown in Nos. 6 and 7, in which the dicrotism is nearly obliterated by the oxygen.

On the other hand, dicrotism may be developed by increasing the capillary resistance, as in No. 8, in which a pulse previously not dicrotic is rendered so by holding the breath.

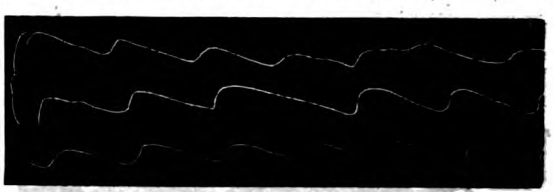


No. 8.—Dicrotism developed by holding the breath.

It may also be developed by giving increased vigor to the systole, and thus propelling the wave of blood with such force that it will rebound when it meets the resistance of the capillaries. This is shown in the tracings marked 9, taken from a medical gentleman who is suffering from some obscure neuralgic affection of the stomach, which compels him to use enormous quantities of morphine. The normal tracings are exceedingly feeble, merely wavy lines. Under the inhalation of oxygen a considerable volume of the pulse is developed, and it has become markedly dicrotic; but it is not as regular and even as it was before the oxygen was administered. Perhaps if a larger quantity of the gas had been inhaled greater steadiness and regularity would have been attained, inasmuch as oxygen, like other cardiac sedatives, seems usually to give strength, firmness, and regularity to the pulse when weak, fluttering, and irregular from disease. This is often very obvious to the finger, a few minutes being sufficient to change entirely the character of the pulse. I have here two sets of tracings by which this is strikingly illustrated. The first, marked 10, is from the pulse of a lady suffering from nervous debility growing out of uterine disease. It is excessively irregular, and to the finger seemed to be intermittent, but the tracing shows at those points a feeble beat. The inhalation of five gallons of oxygen,



No. 9.—Volume increased and dicrotism developed by inhaling oxygen.

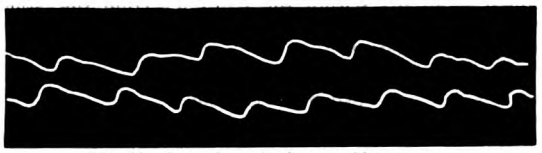


No. 10.—Irregular pulse rendered regular by oxygen.

occupying perhaps ten minutes, resulted in the perfectly regular pulse shown in the third tracing.

The second set, marked 11, were taken from a man whose health is shattered by masturbation. No two

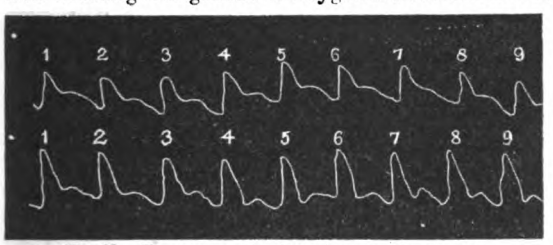
beats are of the same length or the same character. The inhalation of a few gallons of oxygen gave a trac-



No. 11.—Irregular pulse improved by oxygen.

ing which presents a marked improvement. The beats are of the same length, and but for a slight deviation from a straight line, caused by muscular contraction, the tracing would be remarkably regular.

In a small proportion of cases oxygen *quickens* the pulse. It is probable that from some peculiar condition of the system the gas acts merely as a stimulant. Occasional deviations from their usual action are exhibited by all remedies, and to this rule oxygen is no exception. I have here a tracing, No. 12, from a patient having emphysema. Before inhaling the pulse was 96, after inhaling four gallons of oxygen it had risen to 102.



No. 12.—Frequency and volume increased by oxygen.

The height of the stroke is nearly doubled, but the suddenness with which the line descends shows a very low degree of tension. It is, in fact, an irritable pulse, such as is produced by a small quantity of blood propelled with great velocity and in a compact mass. The dicrotism is markedly increased, as we should naturally expect, for the rebound must be in proportion to the force of incidence.

The duration of the effect of oxygen upon the pulse is a point which I have had comparatively little opportunity to determine. My observations having been almost wholly upon office patients, it was impossible, for obvious reasons, to follow up this line of inquiry with any degree of success. In the few cases, however, in which this point has been noted, I have found the duration to vary from a few moments to several hours, and in a number of cases the effect has continued until the following day.

In some cases oxygen seems to be without any effect whatever upon the pulse. When this is the case, it is probably not absorbed, owing to some unknown condition of the blood. Whatever this condition may be, it is often very transient, so that a pulse which is entirely unaffected to-day will perhaps lose sixteen beats under apparently the same conditions to-morrow. Possibly the key to this may be found in the observation of Chevreul, that oxygen is more readily absorbed when the blood is unusually alkaline. In a few cases I have given alkalies, and have fancied that the tonic effect of the gas was afterwards more marked; but my observations have not been sufficiently numerous to enable me to speak decidedly upon this point.

The quantity of oxygen given in the observations forming the basis of this paper was generally about eight gallons. I have not usually observed that the effect was increased by giving beyond that amount at a single sitting. Care was taken to have the conditions similar in the comparative observations. Patients who had been walking were allowed to rest, and everything calculated to produce alarm or excitement was avoided. When the sphygmograph was employed, its nature and use were first explained, a precaution quite necessary in the case of nervous persons, and the comparative observations were made without removing the instrument, or changing in any way its adjustment.

With regard to the facts presented in this paper, Mr. President, I can speak with confidence. They are of such a character that with ordinary care in observing them there is little room for error. But my interpretations of these facts I present with diffidence. The field is a new one, and, so far as I am aware, heretofore unexplored. It may well be that observations from other sources will show that I am in error in the deductions I have made, in which case I shall be the first to welcome the more mature views which will take their place.

Original Communications.

CONGENITAL HYPERTROPHY OF THE TONGUE—OPERATION.

By GURDON BUCK, M.D.,

SURGEON TO NEW YORK HOSPITAL AND ST. LUKE'S HOSPITAL.

Mary Jane C., nine years old, native of Connecticut, of healthy family and good constitution, admitted into St. Luke's Hospital May 21st, 1866, with hypertrophy of the tongue, which her mother states has existed from birth, its increase having gone on proportionately with her general growth.

The tongue is habitually protruded about two inches beyond the lips. It expands laterally, so as to stretch the angles of the mouth, which somewhat overlap it. Its thickness is more than one inch, its breadth two inches and three-eighths, and its circumference four inches and five-eighths. Its upper surface is covered with a yellowish brown coat that on drying is detached and falls off in scales. The protruding portion is firm, hard, and painless; the portion within the mouth, though of full size, is in other respects normal. The under-lip hangs over upon the chin from the pressure of the tongue. Patient is able to protrude the tongue about four inches beyond the lips.

Fig. 1.

The lower front teeth are depressed forwards nearly to a horizontal position, and are thickly incrusted with

tartar, so as to be more than double their natural size. This is true of all the lower incisors and canine teeth. It is remarkable that articulation is very little affected. She attends school, and recites and sings with her fellow-pupils. The sublingual and submaxillary glands are not enlarged. Her aspect and general health are good. (See Fig. 1.)

OPERATION—MAY 26TH.

After etherization the following operation was performed: The tongue being seized with a vulsellum, and drawn forward out of the mouth, a strong double ligature, two feet in length, armed at each end with a large-sized curved needle, was passed from below upward through the edge of the tongue, far back on both sides, at opposite points. One of the ligatures was then cut in the middle, and the ends of each half tied together to form a loop with which to hold the tongue forward, and prevent its retracting within the mouth. The other ligature was kept in reserve, to be used as a suture in approximating the lateral flaps which were about to be formed. The tongue being now drawn forward, and spread out laterally by the loops held by an assistant on either side, was transfixed from below upward in its middle, as far back as the teeth would permit, with a sharp-pointed bistoury, and a lateral flap formed on the left side by cutting outward and forward. The right flap was completed by applying the knife at the edge of the tongue, and cutting in a reversed direction from without inward, and before backward. The arteries spurted briskly, but were secured in the usual manner by three ligatures. The free oozing from the cut surfaces was controlled by the pressure of the lateral flaps, which were brought together and secured by sutures, the principal suture being the ligature held in reserve for that purpose. The complete control of the tongue maintained by the loops used for the purpose permitted the operation to be performed with as much promptness as an ordinary amputation of a limb. The method by lateral flaps employed in this case left the stump well shaped in respect of its breadth; but I was not without some misgivings in respect of its thickness vertically. The protruding part of the tongue being out of the way, it now became apparent that the lower jaw in front had undergone a change of form in consequence of the presence of the tongue. The upper and lower teeth came in contact no farther forward than the first molar teeth on both sides. Anterior to this point the teeth were more than one inch apart in the median line.

May 27th.—Pulse 126. Surface a little hot and dry. Ordered

Spirit. mindereri, ʒ ij,
Tinct. aconit. rad. gtt. i,

every four hours. Had slept well. No severe pain. No hemorrhage. End of tongue situated between teeth one inch thick.

May 28th.—Pulse 120. Slept well. Takes nourishment well. Considerable swelling of tongue has taken place, with a livid, ashy aspect of the protruding portion. Breath very fetid. Right side of jaw swollen. Swallows milk with some difficulty. Ordered half ounce of wine every four hours, and mouth-wash of dilute permanganate of potash.

May 29th.—Pulse 126. Swelling same. Flaps have separated; their edges are sloughy. Appetite good.

May 31st.—Pulse 126. Swelling abating. Sloughs separating. Deglutition improved. General condition satisfactory. In the subsequent progress of the case no considerable loss of parts followed the sloughing. Healthy action was gradually re-established, and on the 18th June cicatrization was complete. The end of the tongue, however, still being too large to be retained habitually within the teeth, a second operation was judged necessary to remove the defect, and was performed as follows:—

SECOND OPERATION.

After the administration of ether, a strong ligature was passed transversely through the tongue far back, for the purpose of controling and holding it forward. The tongue itself being seized with a vulsellum and compressed laterally, its vertical thickness was thereby increased, while a wedge-shaped portion was removed by transfixing the tongue laterally midway between its upper and lower surface with a long, sharp-pointed knife, and cutting forward and downward through its under surface. Then applying the edge of the knife upon the upper surface, opposite to the end of the underflap just made, and cutting backward and downward to where the first incision started, the upper flap was formed. After ligating two or three arteries that spurted freely, both flaps, with their edges, were brought together and secured by interrupted thread sutures.

On the second day following the operation, a good deal of swelling of the tongue had taken place, with considerable febrile reaction. Pulse 124. Skin hot and dry.

On the seventh day, all the sutures had been removed successively; no sloughing had taken place nor any separation of the flaps, as occurred after the first operation. Swelling having mostly subsided, the tongue is easily retained within the teeth, deglutition is easy, and patient sits up most of the day.

Convalescence progressed favorably till about the 10th of July, when patient began to complain of sore-throat, and to have fever, accompanied with restlessness, loss of appetite, &c.

July 12th.—The submaxillary glands are hard and tender, and the upper part of the neck much swollen externally.

July 16th.—Tongue is also a good deal swollen, rendering articulation very indistinct; deglutition is very difficult, and saliva flows freely from the mouth. Pulse 144. Flaxseed poultices are kept constantly applied to the chin and throat. Dover powder is given at bed-time.

July 19th.—The swelling is softening, and fluctuating points are perceptible. A spontaneous opening formed under the base of the tongue, and discharged pus freely into the mouth, affording great relief to the patient, and was followed by an abatement of the swelling and a very decided amelioration of all the symptoms. After this her recovery was rapid.

Before leaving the hospital, Mr. J. A. Bishop, dentist to St. Luke's, examined patient's mouth, and removed the incrustation of tartar from the teeth. Patient was also fitted with an elastic band, adapted to make upward pressure upon the lower jaw, with the view of aiding the restoration of the anterior portion of the lower jaw to its normal relations with the upper jaw, and re-establishing the contact of the front teeth with each other. She was directed to wear this bandage as much of the time as she could.

July 27th.—Patient was discharged, and returned to her home in Connecticut.

In the month of July, 1869, the author had an opportunity of examining this patient, and found her in a very favorable condition, as follows: The tongue, occupying the floor of the mouth, was of natural size, and held *in situ* by its inferior connections. When

the act of protrusion was attempted, it bowed itself upward and somewhat forward; its free extremity was rounded and thinned at its edges. The front teeth, above and below, had approximated, and were scarcely half an inch apart. Articulation was good and not noticeably affected. She attended school, and maintained a high standing in all her recitations as well as in vocal music. (See Fig. 2.)

Fig. 2.

Remarks.—The experience afforded by this case suggests to the author the following conclusions as to the best method of operating for hypertrophy of the tongue. The reduction of the excess in thickness rather than breadth of the organ being the important object aimed at in the operation, this is best accomplished by removing the redundant portion by transverse rather than vertical sections. In the case above narrated, a single operation, performed according to the method employed in the second operation, would have sufficed. The following specific directions, it is believed, may be advantageously followed in this operation: A strong ligature traversing the tongue, far back, is the most reliable mode of controlling the tongue and preventing its retracting within the mouth. The patient's head resting against the breast of an assistant, is held steady by one hand on each side, with the forefinger hooked in the angle of the mouth and retracting it. An additional assistant on either side holds the tongue forward by drawing upon the ends of the ligature traversing the tongue. The operator seizing the protruding portion of the tongue on either side with a vulsellum, compresses it laterally, and thus increases its thickness vertically. With a straight, long-bladed knife he transfixes the tongue far back within the mouth, midway between its upper and lower surfaces, and cutting forwards and downwards, forms the inferior flap. The superior flap is to be formed in the reverse direction. Applying the middle of the edge of the knife to the upper surface of the tongue, opposite to the end of the flap just formed, so that they shall be of equal length, he cuts backward and downward, and terminates this section where the first began. The tongue during the action of the knife being compressed laterally, the extremities of the flaps will be rounded and will correspond to each other. The tongue being under perfect control by means of the ligature traversing it, the bleeding arteries may be secured with almost the same facility as after the amputation of a limb. The flaps are to be approximated and secured with sutures in the usual manner. An important advantage of this method is, that the frenum linguæ not being involved in the section of the tongue, continues to perform its office undisturbed.

No. 46 W. Twenty-ninth St., N. Y.

OPERATION FOR THE RADICAL CURE OF HERNIA.

By C. C. F. GAY, M.D.,

Surgeon to the Buffalo General Hospital.

On April 22d, 1870, Charles Walls, aged eleven years, entered the surgical ward of the Hospital with double scrotal hernia, quite large, being congenital and reducible. The external ring was sufficiently large to admit two fingers of the hand.

On April 29th, I operated upon the right side, and six months thereafter there is, and has been, no escape of intestine from the abdominal cavity. My operation, it is believed, differs from that of any other heretofore made. I obtained the idea from Dr. Chisolm, of Charleston, S. C., and from Dr. Armsby, of Albany, N. Y. By conjoining the two methods separately proposed by these two gentlemen, the operation is made successful. Silver wire was used subcutaneously, after the plan suggested by Dr. Chisolm, and at the same time the silk seton was introduced, as recommended by Dr. Armsby.

The only instrument used was a strong, slightly-curved needle, about four and a half inches in length, with an eye at its point. To the needle was attached a strong handle.

Reducing the hernia, I gathered up upon the left index finger a fold of scrotum, carrying this before the finger to the margin of the abdominal ring. The needle was then thrust through the inferior column of the ring, its point carried over the superior column and out though the integuments, about one inch above the margin of the superior column; then threading the needle with silver wire, it was drawn back into the scrotum, and without entirely withdrawing it from the scrotal integument it was returned over the border of the inferior column, beneath and through the margin of the superior column, thus making the point of exit to correspond to the point of entrance; then removing the needle and twisting the wire, the ring was found to be sufficiently closed to prevent escape of intestine. I did not cut the wire after twisting it, and permit the end to escape beneath the integuments, but left the end projecting one inch or more in length. The next step in the operation was to introduce the silk seton. The seton was composed of six strands of ordinary-sized silk thread. When introduced, it extended from the fundus of the scrotum to two inches above the superior column of the ring, and was inserted by the same needle used in introducing the wire ligature. In inserting it, I raised upon the forefinger the scrotum at its fundus, and carried it up to the ring, partially invaginating it; then just behind the finger thrust the needle armed with the seton through the scrotum, through the superior column of the ring, and out through the integuments. Tying the ends of the seton it was allowed to remain until the tenth day. After removing it, the silver wire was twisted a little more tightly and clipped short, so that it disappeared from view beneath the integuments. There were no consti-

tutional symptoms after the operation, but considerable pain accompanied the local inflammation.

I operated by this conjoint method because I believed the wire ligature alone insufficient to effect a radical cure; that the wire alone would cause no local inflammation, but would act only mechanically to hold the columns of the ring in apposition; therefore the seton was used in order to excite local inflammation sufficient to agglutinate the parts permanently together.

The patient left the Hospital, and afterwards was treated by Dr. Boardman of this city for conjunctivitis.

On September 15th, or about this date, Dr. B., observing the wire about to ulcerate through the integuments, cut it out. On September 22d I examined the patient and found the ring closed and the cure perfect, there never having been at any time since the operation escape of the intestine.

Had the wire alone been employed, as recommended by Dr. Chisolm, I am of opinion that upon the liberation and escape of the wire the columns of the ring would have separated sufficiently to have permitted the descent of the intestine. The termination and successful result of the operation fully justify the method adopted.

HISTORY AND PRESENT STATE OF ELECTRO-SURGERY.

By GEO. M. BEARD, M.D.,

OF NEW YORK.

Electro-Surgery is that branch of electro-therapeutics which includes the electrical treatment of the diseases commonly known as surgical.

The principal surgical diseases and indications for which electricity, in its various forms and by its diverse methods of application, has been found of service, are:—

Aneurisms; varicose veins; strictures; hydatids of the liver; goitre; removal of tumors; cauterization of diseased surfaces; killing nerves; discussion of tumors; ulcers; fistulæ and sinuses; serous effusions; orchitis; enlargement of the prostate; *sprains; spondylitis* (Pott's disease); *pseudoarthrosis*; *hernia; morbus coxarius; toothache; hæmorrhoids; club-foot; exploration of wounds; dissolution of vesical calculi; extraction of foreign bodies; removal of poisonous metals; local anæsthesia.*

It was in the year 1825,* when the cause of electro-therapeutics seemed hopelessly lost, that Sarlandière† called renewed attention to this despised department, by proposing the employment of *electro-puncture*, in order to bring the current more directly to bear on the deeper tissues. The first experiments were made with statical electricity. The subject was afterwards studied by Magendie, who used *electro-puncture* with the galvanic current (galvano-puncture) in the treatment of various diseases. At first electro-puncture was used medically more than surgically. The treatment of aneurisms by this method was of a later date. The idea of causing coagulation of the blood by galvano-puncture was originally suggested by Scudamore, and in 1831, Guérard, Pravaz, and Leroy d'Etiolles proposed the treatment of aneurisms by this method, which was first practised by B. Phillips, about the year 1832.‡ In 1838 Liston became interested in the subject, and in 1839 Schuster successfully employed electro-puncture for the treatment of hydrocele, and other serous effusions, and in 1843 he reported his successes to the French Academy.

In 1839 and the following year also, Crussel, whose name is so prominent a figure in the history of electro-surgery, began his investigations on electrolysis. His experiments excited little interest in the profession. In 1843, also, Steinheil and Heider suggested the theory that the nerves of the teeth might be killed by placing a platinum wire, heated by the passage of a galvanic current, in the cavity; and in 1845 Heider first successfully employed this method. He used for this purpose one very large element of Grove. The operation took but a few seconds. In 1846, Crussel, whose name, as we have seen, is also to be remembered as the founder of electrolytic treatment, successfully removed, by the heated platinum wire, a "large fungus hæmatodes, situated in the frontal and ocular region."

In the same year, Petrequin, of Lyons, obtained the first successful result in the treatment of aneurisms by galvano-puncture. About this time also the same treatment was used by Bucci of Italy. The year 1846 may therefore be regarded as one of special significance in the history of electro-surgery.

In 1847, Bertani and Milani first treated varicose veins by galvano-puncture. In the same year Crussel published his method of treating ulcers by availing himself of the electrolytic powers of the galvanic current.

In 1852, Ciniselli, who still cultivates with distinguished success the department of electrolysis, first established by experiment that *the alkalies appear at the negative, and the acids at the positive pole.*

A great and important impulse was given to galvano-cautery by Middeldorpf, who, in 1854, published his celebrated work on the subject.*

In 1855, Demarquay removed a swelling of the submaxillary gland by galvano-puncture. In the same year Vergnes and Poey published their experiments on the removal of poisonous metals from the body by the electro-chemical bath.

In 1856, Boulu caused resolution of tumors in a number of cases by magneto-electricity applied by means of metallic disks. In the same year, Meding extracted mercury from a patient who had long suffered from mercurial poisoning, by means of the electro-chemical bath.

In 1858 and '59, Zsigmondi published the result of his successful experience with galvano-cautery after the system of Middeldorpf. In 1859, also, Delstanche Lehmann, Burdel, and Thevissen reported successes in the treatment of hydrocele by *farado-puncture.* In 1861, Braun and Von Grunewald introduced the galvano-cautery into gynæcology, where it has since been employed for the removal of polypi, excision of the cervix, etc. Both in the extent and the variety of his operations in this department Middeldorpf far surpassed all his predecessors. He devised a powerful, though somewhat bulky apparatus, as well as various burners and loops, for operating on different parts and organs of the body.

Galvano-cautery has been subsequently studied by various surgeons, and in different countries and with success; but up to the present time the work of Middeldorpf is the leading systematic treatise that has yet appeared on the subject. Middeldorpf is therefore to galvano-cautery what Duchenne is to localized faradization, or Remak to central galvanization. In 1867, Althaus† revived the attention of surgeons to the surgical powers of electricity, by reports of successful experiments in the treatment of nævi and tumors of various kinds by electrolyzation.

* Two years previously (1823), Prevost and Dumas had attempted with some success the dissolution of calculi of the bladder in animals.
† Mémoires sur l'électro-puncture. Paris, 1825.
‡ Erichsen's Surgery, p. 518.

* Die Galvano-caustic. Breslau, 1854.
† Tumors and other Surgical Diseases, 1867.

In the same year Mallez and Tripier published some very remarkable results in the treatment of strictures of the urethra after the method originally proposed by Crussel.

Surgical, unlike medical electricity, has been studied and pursued mainly by men of science, and the progress that has been made in it has been much more frequently the direct result of scientific observation and experiment. Those physicians who have made eras in medical electricity have done so by improving, developing, and introducing to the profession methods of treatment which, either by charlatans or others, had been substantially known and practised before them.

ELECTROLYSIS.

Electrolysis (ἤλεκτρον and λύω, to disengage) *is the act of decomposing a compound substance by electricity.*

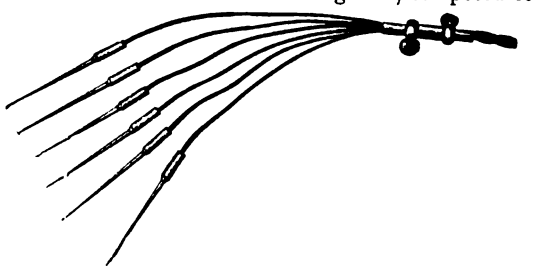
This electro-chemical decomposition takes place at both poles, but with different products and manifestations, according to the nature of the substance acted upon. If, for example, the two poles are introduced by needles into a blood-vessel, *acids*, with albumen, fibrin, etc., appear at the positive, and *alkalies*, watery extracts, iron, and coloring matter at the negative pole. When water is decomposed by the action of the current, *acids and oxygen* appear at the positive, and alkalies and hydrogen at the negative pole. Electrolytic action is chiefly obtained by the *galvanic current*, although the *magneto-electric* current, when generated in a properly constructed apparatus, has a decided electrolytic power. Statical electricity also has a feeble electrolytic power. For the purposes of electrolysis, intensity with moderate or fair quantity is required, such as is obtained by a considerable number of elements of medium size. The chemical effects of *statical electricity* were first investigated by Drs. Priestly and Cavendish in 1784, and the decomposition of water by passing through it a succession of discharges of statical electricity was first discovered in 1789 by Messrs Dieman, Paetz, Van Troostwyck, and Cuthbertson.

The electrolysis of water by the galvanic current was discovered in 1801 by Nicholson and Carlisle. Electrolysis of various inorganic substances was subsequently investigated by Sir Humphrey Davy, but especially by Faraday,* whose published researches in this department constitute one of the most interesting and valuable contributions to experimental science that ever proceeded from the pen of man.

Some of the uses of electrolysis—such as the discussion of malignant tumors—require more quantity of electricity than others. Any good combination of Daniell's or Bunsen's elements, or Siemen-Halske's elements, or of Smee's elements, of a good size, such as Kidder uses in his galvanic apparatus, will furnish sufficient quantity for nearly any required purpose.

The number of elements to be employed depends on the special purpose in hand. The general rule is, the larger the extent of tissue to be acted upon, or the harder it is, the greater the quantity or intensity of electricity required.

Deficiency of quantity or intensity in a battery may, within certain limits, be compensated by protracted application. The electrolytic power of any battery may be tested by the galvanometer, or by the rapidity and extent of its action on iodide of potassium, or acetate of lead, or chloride of sodium, or on the white of an egg, or on a piece of raw beef. For producing electrolysis in tissues beneath the skin, fine needles of gold or gilded steel are used. The conductors may be composed of two, four, six, eight, or more needles. Althaus has employed a conductor, a modification of which is represented in the following cut. This consists of a conducting wire, composed of



a number of small wires twisted, with a number of branches, each one of which is so arranged that it can be attached to a gilded needle after it has been introduced into the part to be treated. The needles should be insulated with vulcanite or some preparation of rubber and shellac for a portion of their length, so that they may not act on the skin, and so cause unnecessary pain and subsequent inflammation.

ANEURISMS.

The object in the electrolytic treatment of aneurisms is to secure a gradual deposit of the layers of fibrine. For this purpose the negative pole is by some thought preferable, although successful results have been obtained by the positive pole, or by both combined.

Two or three needles, connected with the negative pole by a subdivided electrode, are introduced into the aneurism, while a sponge electrode is applied to the surface near by. The length of the applications may range between 5 to 40 or 50 minutes, according to the strength of the battery and condition of the aneurism. From one to five operations are usually sufficient.

It is necessary to use an anæsthetic. Of all the (nearly 100) cases of aneurism treated by electrolysis, thus far reported, a little more than half have been successful. It is probable that future experiments, with improved apparatus and the better knowledge that comes from accumulating experience, will exhibit a greater proportion of successes.

VARICOSE VEINS.

Varicose veins have been treated electrolytically, and with both the positive and negative poles. Here I may remark that, in electro-surgery as in electro-medicine, the differential indications for the use of the poles are far, very far, from being reduced to an exact science. Electrolytic action takes place at both poles, and on the whole is more powerful at the negative; but is greatly modified by the nature of the substance acted on or the material of which the electrode is composed.

STRICTURES OF THE URETHRA.

Electrolysis for stricture was first used by Crussel, and subsequently by Willebrand and Wertheimer. The most important and successful results have been obtained by Mallez, Tripier,* and Brenner.† Their method of application is to introduce an insulated sound with a metallic extremity to the seat of the stricture, connecting it with the negative pole, while the positive is applied to the inner side of the thigh by a moistened sponge electrode. Usually from one to

* Experimental Researches in Electricity, London, 1839, 1844, and 1855. See also Noad's Lectures on Electricity, London, 1844.

* De la guérison durable de rétrécissement de l'urèthre. Paris, 1867.

† Untersuchungen und Beobachtungen auf dem Gebiete der Electrotherapie. Leipzig, 1868 and 1869. Bd. II, p. 263.

four applications are sufficient to overcome the stricture and allow the ready use of sounds. The operation is but little painful, and only in a minority of cases was there any hemorrhage. Mallez and Tripier have treated in this way 31, and Brenner 13 cases, and both agree that the operation is preferable to urethrotomy. Only a moderate strength of current—from 10 to 15 elements—is required.

In two of Brenner's cases febrile symptoms followed the operation.

In two of his cases, also, perineal abscess resulted. Out of the 44 cases, 2 proved fatal: one under Mallez and Tripier, from inflammation and fever, and one of Brenner's, where the autopsy showed that the electrolytic treatment was not the only cause of death, though it might have hastened it, since the patient was previously suffering from urethro-scrotal fistula.

Dr. Chadsey* has reported a case of retention of the urine caused by hard work and exposure to cold that yielded to faradization, with the positive pole applied against the stricture for 20 minutes by means of a knitting-needle in a gum elastic catheter.

In this case the result was due to the mechanical effects of the current, and not to any electrolytic action.

HYDATIDS OF THE LIVER.

According to Althaus, Dunham and Forster have treated eight cases of hydatid tumors of the liver with success by electrolysis.

GOITRE.

Makenzie of London speaks favorably of the electrolytic treatment of goitre in cases that are not of too long standing. The cystic variety he has found to yield more rapidly than the solid.

EXTIRPATION OF TUMORS AND DISEASED PARTS.

That polypi of the larynx and nasal passages can be very conveniently removed by the galvano-cautery is now well established, and, so far as is known, all who have ever attempted this method of treatment are pleased with and disposed to return to it. The same method has been employed by Jacoby† for the removal of growths in the external auditory canal.

Brenner‡ has given full details of a successful case of amputation of a diseased tongue, in a patient 62 years of age, by the galvano-cautery, and Dr. James Adams, by the same method, has removed an epithelioma of the side of the tongue without loss of blood.§

Dr. Robert Lee reports a case of scirrhus of the right breast that had reappeared after two operations.

Drs. Kammerer and Guleke‖ report two successful amputations of the neck of the uterus by the galvano-cautery.

DISCUSSION OF TUMORS.

Tumors may be discussed by all forms of electricity, and in all methods of application.

1st. By galvanic chains or belts. 2d. Faradization. 3d. Galvanization. 4th. Electrolyzation. Of these methods the last is decidedly the most effective; and yet that very decided results in the discussion of tumors can be obtained by simple external faradization frequently repeated we have abundantly demonstrated in a variety of instances. Meyer, Hassenstein, Boulu, and Duchenne report similar experience. The tumors most disposed to yield to external faradization are the glandular and cystic varieties. *Lipoma* is the most obstinate of all the varieties on which we have experimented.

Nævi have been treated electrolytically and with absolute success by Althaus,* etc. Of *erectile* tumors we have records of two cases that have been treated by electricity. A large vascular tumor was removed during the last year, at the hospital of Gesu Maria, Italy, by galvano-puncture. The details of the case we have not seen. Very recently Drs. Sass and Lincoln† of this city have very successfully treated a venous erectile tumor of the neck.

MALIGNANT TUMORS.

The electrolytic treatment of cancer has for several years been studied by Althaus, who states that under treatment by the negative pole "the peculiar lancinating pains of cancer generally seem to disappear, or at least to diminish considerably, soon after the commencement of the electrolytic treatment, and long before the whole tumor is destroyed."

Sept. 1, 1866, we treated by faradization a case of tumor of the right breast that was quite hard, and was accompanied by severe lancinating pains. It had gradually increased in size until it was about as large as a hen's egg. The patient stated that a number of medical men of the West had seen the tumor, and all had pronounced it to be a cancer, and had advised its extirpation. As an experiment purely, and in the hope only of being able to relieve temporarily the pain, we tried faradization of the tumor. After the second application it became softer, there was a manifest diminution in size, and the pain was notably diminished.

After the fifth application, Sept. 14th, both the tumor and the pain had entirely disappeared. The patient left the city overjoyed with the result. Since that time we have heard nothing from her, and for that reason the case loses much of its scientific interest. So far as it goes it is an encouragement for other experiments in the same line. That faradization can relieve the lancinating pains of cancer we have demonstrated in the case of a lady of middle age, who in 1867 consulted us for a tumor of the right breast, which for a number of months had caused her great distress. The diagnosis of malignant tumor was confirmed by Dr. W. H. Van Buren, who also advised against an operation. The patient was treated by general and localized faradization, with the result of greatly relieving her pain as well as improving the appetite, sleep, and muscular strength.

The patient left the city, and we had no opportunity to give special attention to the tumor.

The same department has also been studied by Drs. Neftel,‡ Jacobi§ (who states that he has seen suffocation produced during the treatment), and others.

FARADO-ELECTROLYZATION.

I have used this term to designate the *simultaneous* use of external faradization, and electrolyzation with needles, which method I am now employing in a case of undoubted scirrhus of the breast, referred to me by Dr. Stephen Rogers. Sloughing has appeared, and the tumor has apparently been made smaller and softer by the treatment, and the pains have certainly diminished. The patient is still under treatment, and will test, so far as a single case can, the comparative advantages of the different methods.

---

* N. Y. Medical Journal, Feb., 1869, p. 574.
† Archiv für Ohrenheilkunde, V. I.

* Tumors and other Surgical Diseases. London, 1867.
† MEDICAL RECORD, Dec. 15, 1870.
‡ MED. RECORD, Oct., 1870.
§ *Ibid.*, Sept. 1st, 1869, and October, 1870.

The facts variously accumulated and now accumulating on this subject seem to justify these conclusions:—

1st. Malignant tumors, scirrhous and encephaloid—at least in certain stages, and in a proportion of cases—may be discussed, both by external faradization and electrolyzation—possibly also by external galvanization. Of these methods, faradization is the more convenient, and is but little, if at all, painful, and does not interfere with ordinary duties; but in most cases of scirrhus it would probably fail. Electrolyzation is the most rapid and effective; but it requires local and general anæsthesia, and may produce suppuration and unpleasant after-effects that may require absolute rest.

2d. Both of these methods may have a decided effect in relieving the pain, even when they do not succeed in entirely destroying the tumor.

3d. Patients afflicted with malignant tumors, as with many other serious diseases, would probably be susceptible of improvement in their general condition by general faradization, even when no attention is given to the local disease.

4th. The great and important questions, whether the tumors return as speedily as after removal with the knife, or whether they return at all, or what proportion of cases will be successful, and in how advanced stages, can only be answered by a large number of cases carefully treated by various methods, and closely watched for years by observers in whose capacity and honesty the profession repose unfaltering confidence.

ULCERS.

The earliest systematic attempts to treat ulcers by electricity were made by Crussel, in 1847, although as early as 1803 Mongiardini and Lando had treated gangrene electrically.

The same treatment has been used in syphilitic ulcers by Kyber of Cronstadt, Rosenberger of St. Petersburg, and in the majority of their reported cases with success.

Spencer Wells has also used galvanism with success in the treatment of ulcers. He employed zinc and copper, or silver plates connected with a wire.

Ulcers may be treated with both currents. The best form of electrodes is metallic disks or plates. These can be varied in shape or size according to the locality of the ulcer. Stable applications should be used, with a current very gradually *increasing*. The applications should be short, and need not be excessively painful. In some cases decided results may follow a single application of electricity to an ulcerated surface. Ulcers may also be cauterized by the galvano-cautery.

In the treatment of ulcers, and indeed of many conditions, it is a convenience to have an electrode kept in a fixed position without the aid of the physician or of an assistant. For this purpose I have devised a series of adjustable electrodes, provided with rubber bands of different lengths which can be passed around the body. They may be of various sizes, and like other electrodes may be covered with sponge, linen, flannel, or chamois. The smaller sizes are for the arms and legs, and back of neck; the larger for the back and coccyx, and may be used in general electrization instead of the copper plate at the feet. Of the other surgical diseases I have only space to remark that *fistula* and *sinuses* have been treated by the galvano-cautery; that *serous effusions*, synovitis, hydrocele, pleurisy, yield sometimes very rapidly to faradization, galvanization, or to electrolyzation; that *orchitis*,* acute and subacute, has been satisfactorily treated by galvanization; that *sprains* are relieved both by galvanization and faradization; and that the slight anæsthetic effects of faradization with strong currents are so demonstrable that it seems surprising that they should ever have been seriously doubted.

An important distinction between medical and surgical electricity is this, that nearly all the surgical diseases for which electricity is employed have been treated with more or less success by other methods, while in many of the medical diseases in which electrization has been most successful, it has been the chief, and in some the only dependence.

Finally, it should not be forgotten that the surgical successes achieved by electricity have been of great service to electro-therapeutics in general. A surgical operation appeals to the eye and to mechanical skill, while medicine appeals more to the higher and rarer qualities of reason and imagination. Many who fail to comprehend a complex medical fact or principle may be fascinated and carried to enthusiasm by whatever strikes the senses. Hence we find that the suggestion of electro-puncture in 1825 revived an interest in electricity that its purely medical applications failed to sustain, and from that time to the present the fortunate operations of galvano-cautery and electrolysis have aroused the attention of many who had no faith in and no comprehension of the remarkable powers of electricity over nutrition.

* The electrical treatment of orchitis has been studied by Drs. Jules Chéron and Moreau-Wolf (*Du Traitement de l'Orchite*, etc. Paris, 1869.) In one case of chronic orchitis I have confirmed the results which they claim.

Progress of Medical Science.

UROMALANINE, a blackish brown powder, void of form and color—is as interesting to the pathologist as its congener is to the physiologist. It owes its name and quantitative analysis to Dr. Thudichum. This observer obtained it in large quantities by the chemolysis and physiolysis of urine. He gives it the very complex formula, $C_{36}H_{43}N_7O_{10}$. Dr. Smith believes there is very little doubt that this substance is identical with the pigment of the skin in health and disease, and that, when an excess of the compound, from which it is derived, exists in the blood, a parallel excess of this, or rather of an intermediate substance, will occur in the urine. If this be so, all morbid pigmentations of the skin are to be classed in two divisions.

1st. Pigmentations due to temporary excess of uromelanoid pigment or pigment-forming substances in the blood.

2d. Pigmentations due to the abnormal attraction of the normal pigment, or the pigment-forming matter to the skin.

Of the first division he knows of one example only. The morbid pigmentation of the skin, which is the accompaniment and consequence of the accumulation of pigment in the spleen that occurs in some cases of malarious fever—a phenomenon described by Frerichs, in his section on pigment liver, and before him described by Addison. Parenthetically, he would like to know whether it is on record that, in cases of *melanotic cancer*, pigmentation of the skin has been observed. It seems possible that these tumors might act as reservoirs of pigment, just as the spleen has been shown to act; in this case a second example might be added to the first division.

Of the second division very many examples suggest themselves, viz.: lentigo, or freckles; ephelis, or tanning; nævi materni; chromidiosis, a disease mentioned by Hardy; the pigmentation which accompanies long-continued dermatosis; the pigmentation of the nipples of pregnant women; the pigmentation fol-

lowing epigastric applications; the bronze skin of morbus Addisonii.

A Simple Method of Estimating Uromelanine.—Wm. Frank Smith, M.B., Physician to the Sheffield General Infirmary (*Journal of Cutaneous Medicine*), estimates the uromelanine producing substance in the urine as follows:—A given quantity of urine is diluted with an equal measure of distilled water, to this is added a definite quantity of sulphuric acid, sp. gr. 1.843. The mixture is allowed to stand for ten minutes exactly, and then added from a burette to water in a tube connected with a candle-light of constant illuminating power by a simple optical apparatus. At the moment that the light is obscured to a certain extent, indicated by the disappearance of an opaque line, the burette is examined, and the relative quantity of uromelanine read off.

New Method of Corelysis.—G. Passavant (*Arch. f. Ophthalmol.*, XV., I., p. 259 & f.) describes a new method of corelysis (detachment of posterior synechiæ), which he practised with unvarying success in some fifty cases of small adhesion between the iris and lens capsule, and also sometimes between the iris and central portion of the cornea. He makes a small peripheric incision through the cornea, enters with a pair of blunt-toothed iris forceps, seizes the iris near the adhesion, and tears the latter from the lens capsule. No prolapse of iris through the corneal wound had occurred, and a round movable pupil was obtained. In cases where several synechiæ exist several operations are necessary.

Schmidt's Discovery.—Dr. H. D. Schmidt, of New Orleans, La., in his "Microscopical Anatomy of the Human Liver," asserts his priority as the discoverer of the tubular nature of the radicles of the biliary passages. Lately this network has been represented by Legros to be the *bile-secreting* apparatus, while the hepatic cells subserve other functions of the liver.—*St. Louis Med. and Surg. Journal.*

Hæmatoma Auris.—Sanguineous tumor of the external ear has been observed often as a concomitant of insanity. M. Ferrus, in France, and Bird, in Germany, first called attention to it in 1838. Dr. E. R. Hun, of the N. Y. State Lunatic Asylum, reports (*Am. Jour. Insanity*) twenty-four cases of this affection. It occurred twenty-three times in men and only once in women.

Retinal Changes in Bright's Disease.—John Green, Med. Prof. of Ophthalmology in the St. Louis College of Physicians and Surgeons (the St. Louis *Med. and Surg. Journal*), reports four interesting cases of Bright's disease in which the changes in the retina, as revealed by ophthalmoscopic examination, first aroused the suspicion of renal trouble.

These cases illustrate the most important features of the amblyopia of Bright's disease. The one constant subjective symptom is failure of vision, which may be so slight as scarcely to attract notice, or so great as to incapacitate the patient from guiding himself. This may appear at any stage of the disease, and may increase and diminish or even almost entirely disappear after having reached nearly total blindness, while the fatal malady is steadily marching onward to its inevitable termination. It is absolutely painless in all its stages, and is marked by no external sign of inflammation. The diagnosis of albuminous retinitis by the ophthalmoscope is usually a matter of great simplicity. The principal source of possible mistake lies in the close resemblance which some cases of this disease bear to infiltration of the disc of the optic nerve and the retina immediately around it, occurring simultaneously in both eyes from obstructed venous circulation dependent on intra-cranial pressure from effusion, etc.

Stoddart's Chemico-Microscopic Test.—W. Walter Stoddart, F.C.S., Prest. British Pharmaceutical Conference, Liverpool (*Chemist and Druggist*), advocates the subjoined *chemico-microscopic test:* Into an ounce of distilled water drop 10 drops of dilute sulphuric acid (B. P.). To this add 14 grains (or as much as will saturate the acid) of the suspected salt. Filter through paper, and to a little of the filtered solution add a few drops of sulphocyanide of potassium (1.80 grains in 1½ ounces of water). An immediate precipitate of the several alkaloids takes place, each of which is distinct and characteristic. If quinia and cinchonia be present they will be all seen on the slide, becoming more and more distinct during the first hour.

Prolapse of the Umbilical Cord.—Four hundred cases of this difficulty have been collected by Dr. Massmann (*Praktische Arzt*), of which forty came under his own observation in Breslau. Scanzoni has said that prolapse of the umbilical cord happens once in 254 births. Massmann estimates it at one to 123 births. According to Scanzoni, the death of the child occurs in fifty-four per cent. of the cases, while Massmann believes that death happens in forty-five per cent. The child dies asphyxiated.

The Anterior Fontanelle.—Dr. Coggswell reported at Waltham, Mass. (*Boston Med. & Surg. Journal*), a case of a man of 45, in whom the anterior fontanelle and the sagittal suture were open, so that the pulsations of the brain were felt. He was subject to severe headaches, which his wife treated successfully by approximating the edges of the parietal bones by strong manual pressure. When seen, the patient had just had an epileptic attack, but had never suffered from such attacks previously.

Chloral in Midwifery.—Dr. Lambert, late House-Surgeon to the Edinburgh Maternity Hospital (*Edinburgh Med. Journal*), arrives at the subjoined conclusion, in regard to the administration of chloral in cases of labor: Chloral is an agent of great value in relief of pain during parturition. It is demonstrated that a labor can be conducted from its commencement to its termination, without any consciousness on the part of the patient, under the sole influence of chloral. The exhibition of chloral in nowise interferes with the exhibition of chloroform. The proper mode of administering chloral is in fractional doses of 15 grains every quarter of an hour until some effect is produced; and according to the nature of that effect the further administration is to be regulated. Some patients will require doses of one drachm; and it is better to produce an anæsthetic effect by three drachms given in the space of two hours, than by one drachm given singly.

This agent rather promotes uterine contraction, by suspending all reflex actions which tend to counteract the incitability of the centres of organic motion.

Labors under chloral will probably be found to be of shorter duration than when natural. The general conditions under which chloral is to be administered are the same as those which regulate the administration of chloroform, and the rules laid down by the late Sir James Y. Simpson, M. D., in connection with this subject must be rigidly adhered to.

Amputations in Pennsylvania Hospital during Forty Years.—In 749 amputations, upon 735 patients, performed during the 40 years from 1830 to 1870, 548 were cured, and 186 died, and 1 removed. 500 were primary operations, performed during the first 24 hours after the accident, of which 117 died; 105 were secondary, of which 42 died; 114 were for diseases of a chronic character, of which 27 died; 232 of the patients were under 20 years of age, of whom 206 were cured, and 26 died; 217 were between 20 and 30, of whom 164 were cured, and 53 died; 152 were between 30 and 40, of whom 105 were cured, and 47 died; 87 were between 40 and 50, of whom 56 were cured, and 31 died; 44 were upwards of 50, of whom 23 were cured, and 21 died.

Of 50 arm amputations, 34 were cured and 16 died.

Of 2 elbow-joint amputations, 2 were cured.

Of 48 forearm amputations, 42 were cured and 5 died, 1 removed by request.

Of 23 wrist and partial of hand amputations, 23 were cured.

Of the 321 amputations, 239 were primary; of these 176 were cured, 63 died; 22 were secondary operations, of these 11 were cured and 11 died; 60 were amputations for chronic diseases, of these 51 were cured and 9 died.

61 amputations were done at the joints, of these 44 were cured and 17 died.

134 were amputations of the lower extremities, of these 111 were cured and 23 died.

187 were amputations of the lower extremities, of these 124 were cured and 63 died.

114 patients were under 20 years of age, of these 98 were cured and 16 died.

84 patients were between 20 and 30, of these 63 were cured and 21 died.

65 patients were between 30 and 40, of these 45 were cured and 20 died.

25 patients were between 40 and 50, of these 16 were cured and 9 died.

23 patients were above 50 years of age, of these 7 were cured and 16 died.

Dr. Thomas George Morton, one of the attending surgeons (*Am. Journ. Med. Sciences*), reports that ether has been almost invariably used as the anæsthetic, and no death has, he believes, ever occurred in the hospital from its use; occasionally ether has been combined with chloroform; one sudden death, however, occurred with the use of this mixture, during the removal of a fragment of necrosed bone following a leg amputation; the nitrous oxide gas he has used in very many minor operations, and in 8 amputations of limbs, and has found it satisfactory when the operation was not prolonged.

Uterine Fibroid of the Posterior Wall Successfully Removed.—A Reeves Jackson, M.D., Chicago, Ill. (*Chicago Med. Journal*), recently successfully removed, by surgical treatment, from an unmarried woman, aged twenty-four years, a uterine interstitial fibroid tumor of the posterior wall, about the size of the gravid uterus at the fifth month.

Abdominal Viscera.—In children tubercles in the solid organs of the abdomen rarely give rise to appreciable symptoms, as they are small and disseminated, not impairing materially the function of the part in which they are located. On the other hand, peritoneal and intestinal tubercles, and the enlarged and cheesy mesenteric glands, give rise to symptoms which require description. The most frequent seat of peritoneal tubercles is upon the attached surface of the peritoneum, where they are formed from the connective tissue. They are distinctly seen through the peritoneum, and cause some prominence of it. Exceptionally their seat is upon its free surface. Every portion of the peritoneum, whether visceral, parietal, or omental, is liable to tubercles, but general tuberculization of so extensive a surface does not occur in any one case. The tubercles are spherical or lenticular, and most of them small. Sometimes they are very numerous, but so minute as to be scarcely visible. They are gray or yellow, according to the age. Peritoneal tubercles often produce circumscribed peritonitis, causing adhesion of opposite surfaces. The tubercles in themselves cannot be detected by palpation; but masses or *plaques* composed of tubercles and inflammatory products are sometimes so large that they can be felt through the abdominal walls.

The symptoms of peritoneal tuberculosis are attributable, for the most part, to the peritonitis. Among them may be enumerated abdominal tenderness or pain, meteorism, ascites—usually slight—and derangement of the bowels, commonly diarrhœa. As tubercles in this situation occur, in most cases, subsequently to tubercles elsewhere, the symptoms which have been described are associated with and are subordinate to others.

Synclitism.—Dr. Hugh L. Hodge, of Philadelphia (*Am. Jour. Med. Sciences*), in answer to some clinical remarks by Dr. J. Matthews Duncan, in *Edinburgh Med. Jour.*, on what M. Kueneke terms the synclitic movement of the fetal heart, asserts that synclitism, or parallelism of the plane of the pelvis and of the vagina, is one of his favorite doctrines, and has been taught by him with more or less fulness and precision since the year 1833. His confidence in its truth has been continually strengthened by careful observation.

A Case of Idiopathic Abscess of the Liver.—Dr. Oscar J. Coskery (*Baltimore Med. Journal*) reports a fatal case of idiopathic abscess of the liver, occurring in a German shoemaker, aged 27 years. There are several points of interest connected with this case:—1st. The development of an idiopathic abscess in this climate. Indeed, Murchison calls them tropical abscesses. 2d. The absence of any former attack of dysentery. By many the abscesses are thought to be pyæmic deposits from that disease. 3d. The presence of the phenomenon first pointed out by Mr. Twining, and by him thought to be pathognomonic, the permanent rigidity of the right rectus muscle. To what is this due? He does not think to any special nerve influence, but to the involuntary effort of nature to shield an inflamed and sensitive part. This symptom, however, first caused him to suspect abscess. 4th. The quantity of discharge at first puncture, and the small size of the cavity after death. 5th. The total absence of putrefactive changes in first discharge, after being kept so long. This disposed him to believe bile present, though there was no response to the test. 6th. The total absence of icterus all through. 7th. The total absence of pain anywhere, except immediately over point of puncture, the end of the eleventh rib. 8th. The total absence of coloring-matters of bile in discharge and urine. 9th. The quantity of discharge (90 ounces) during sixteen days subsequent to puncture. 10th. Where did the pus discharged by rectum come from? Certainly not from the abscess in the liver.

Hydrochlorate of Quinia in Hooping-Cough.—Dr. Briedenbach (*Lancet*) calls attention to this remedy in hooping-cough when other means have failed. Binz has already recommended it, and states that it should be administered in comparatively large doses.

FARADIZATION.—A writer in the *Medical News and Library* makes use of Faradization, as a means of diagnosis between hysteric hyperæsthesia and the true neuralgia. It has a strikingly inactive effect in the former, but acts much more slowly, or not at all, in true neuralgia.

THE USE OF RAW MEAT IN DIARRHŒA AND DYSPEPSIA.—Dr. Robert Druitt, M.R.C.P. (*Med. Times and Gazette*), first learned the use of raw meat as a remedy for diarrhœa, from the late Professor Trousseau, in 1851, and since that visit to Paris he has had, with others, abundant opportunities of proving its efficacy. It is useful in infantile "cholera," chronic diarrhœas of children, habitual diarrhœa associated with "marasmus," obstinate vomiting of pregnancy, cases of atrophy, dyspepsia, and mal-nutrition.

WHEN TO GIVE ARTIFICIAL FOOD TO INFANTS.—Dr. Brinton (*Trans. Lond. Obstet. Soc.*), advocates giving artificial food to babies, such as corn-flour with milk, when the first teeth come and the child begins to bite its mother's nipple. When the child's mouth is toothless, its office is to suck the breats. He orders milk and water until the teeth appear, to infants brought up by hand.

THE REMOVAL OF MECKEL'S GANGLION.—The propriety of removing Meckel's ganglion, for the relief of neuralgia of the second branch of the fifth pair of nerves, is discussed by Dr. P. S. Connor, Professor in the Medical College of Ohio (*Am. Journ. Med. Sciences*). Of the whole number of reported operations (13), pain is known to have recurred in seven cases.

REPORTED CASES OF SOLITARY KIDNEY.—The Committee appointed by the Pathological Society of Philadelphia, to collect cases reported of solitary kidney, present twenty-five undoubted cases, in addition to the fourteen of Mosler, making thirty-nine cases collected by them. Of the twenty-five undoubted cases the left was absent in seventeen instances; the right in four; five cases are uncertain; while in Mosler's cases the deformity was found about equally upon the two sides.—(*Amer. Journ. Med. Sciences.*)

A HIGHLY-RECOMMENDED PROSTATIC CATHETER.—Dr. F. F. Maury, Surgeon to the Philadelphia Hospital (*Med. and Surg. Reporter*), recently exhibited and recommended, at his clinique, Dr. T. H. Squire's vertebrated prostatic catheter, which consists of a straight tube terminating in ten metallic caps or vertebræ. The last of the tubes is fenestrated. A wire runs within the tube attached to either end.

This instrument is easy of introduction, and drops naturally to the bas-fond of the bladder, so as to draw off all the urine. Dr. H. Lyle Smith, of Hudson, New York, writes that it has been successful in his hands.

A CASE OF KELOID.—Dr. F. F. Maury, of Phildelphia (*Med. and Surg. Reporter*), has under his observation one of the most rare cases of keloid that has ever presented itself in that city. The patient is a negro, 28 years of age. The huge growth encircles his neck like the foldings of a snake. There are 37 growths, of variable size, of a tomato-like outline upon his body. These tumors have been removed repeatedly, and their recurrence observed.

He regards this affection as undoubtedly keloid, an affection of the skin first described by Alibert in 1810. A section of this tumor resembles the section of a turnip with a fine grain.

MESENTERIC GLANDS.—Though the mesenteric glands undergo similar changes to the bronchial, the symptoms to which they give rise are quite dissimilar. The abdomen, in some patients, retains nearly its normal size; in others it is distended with gas. It does not have the tension and fulness which are so often present in peritoneal tuberculosis. When the disease is somewhat advanced, and the abdominal walls are emaciated, the enlarged mesenteric glands can often be detected by digital examination. The tumor produced by the aggregation of the glands is seated in the umbilical region, and it presents rounded prominences readily appreciable by the touch. The absence of a tumor obviously affords no proof that the glands have escaped the disease, as they may be diseased without being sufficiently voluminous to be detected. The glands are ordinarily more or less tender on pressure.

Extensive disease of the mesenteric glands, interfering materially with the process of assimilation, involves a greater degree of emaciation than would result from the general tubercular affection. The tongue is moist, appetite good, sometimes voracious, and the food is retained; diarrhœa is commonly present, but this is attributable to intestinal inflammation and ulceration, which commonly accompany the glandular disease. The intestines, on account of the depth of the mesentery, and their consequent mobility, are rarely, perhaps never, compressed by the glands; but their movements are sometimes restrained by adhesions. Rarely a softened mesenteric gland forms attachments to the intestines and is evacuated by ulceration. If, in such cases, the intestine becomes detached from the gland, fatal peritonitis results. An occasional result in advanced cases is compression of the ascending cava, causing distension of the veins of the abdominal walls, and lower extremities, and anasarca.

MANAGEMENT OF INGUINAL HERNIA.—Dr. Warren Stone, of New Orleans, La. (*Galveston Med. Journal*), advocates in recent cases of inguinal hernia, the simple operation of section, which consists simply in passing the finger up to the point of stricture, and forcibly thrusting it into it, either lacerating it or dilating it, so as to relieve the bowel. But if these means fail, it is almost as simple to cut down through the integuments and superficial fascia, and to divide the stricture outside of the hernial sac. There is no necessity for making the incision so long as is usual when the sac is opened, though it is well to make it ample. The hernial sac can be exposed without the slightest risk. Its simplicity is not its only advantage. The bowel is more easily returned when enclosed in the serous sac than when exposed to direct manipulation. Serous membranes are easily excited by handling.

CARBONATE OF AMMONIA IN RUBEOLA.—Dr. A. D. Boggs (*Galveston Med. Journal*) writes that he has successfully treated, during the past winter and spring, nineteen cases of measles with carbonate of ammonia. The ages of the patients were as follows:—Under 10 years, 5 cases; between 10 and 15 years, 5 cases; between 15 and 25, 5 cases; between 25 and 40 years, 2 cases; over 40 years, 2 cases.

In every case the ammonia was administered in simple solution, in doses varying from two to ten grains, every two, three, or four hours, according to the age of the patient and severity of attack. In not a single case was there any of the usual sequelæ of this affection, and in all the recovery was rapid and uninterrupted.

The injunction of Dr. Erasmus Wilson was carried out fully, viz.: "It is important, in the administration of ammonia, that it should be given alone; that nothing should be permitted in the diet of the patient that could neutralize its effects, such as acid drinks and fruits."

THE MEDICAL RECORD.

A Semi-Monthly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

New York, January 2, 1871.

THE MEDICAL AND SURGICAL HISTORY OF THE LATE WAR, AND THE REPORT OF SURGEON-GENERAL FOR 1870.

AMONG the Executive documents submitted with the President's Message at the commencement of the third session of the forty-first Congress there is one which is of special interest to us and to the medical profession, namely, the Report of the Surgeon-General for the fiscal year ending June 30, 1870—a copy of which is now before us.

This Report contains among other things an answer to the very important question which we have often heard, viz., Where is the Medical and Surgical History of the War? and is it to be published?

This report states that "the printing of the Medical volume of the first part of the Medical and Surgical History of the War is near completion. This volume embraces the statistical tables representing the sickness, mortality, and discharges from service on Surgeon's Certificate of Disability, of *white* and *colored troops* during the War, and will be a work of nearly seven hundred and fifty (750) pages, quarto. To secure accuracy, the tables were stereotyped as they were finished, and before finally sending them to press they have been thoroughly revised throughout, and every effort made to make them complete. With this volume will be bound the appendix to the first part of the Medical and Surgical History of the War, containing the reports of Medical Directors, and other appended documents—about four hundred (400) pages.

"The whole of the manuscript for the Surgical volume of the first part of the Medical and Surgical History of the War, authorized by the Act of Congress, approved March 3, 1869, is now prepared, and several of the more important subjects that would belong to the second volume, as, for example, the tabular statements, discussions, histories of typical cases (with illustrative wood-cuts and lithographs), of twenty-nine thousand five hundred and seventy-two (29,572) cases of amputations, and four thousand seven hundred and seventy-five (4,775) excisions, are nearly perfected. Besides this, the surgical statistics of the Army for the five years succeeding the war have been consolidated and arranged for publication, and much information has been furnished to authenticate just claims of applicants and to defeat those that were fraudulent under the Act of Congress authorizing the issue of artificial limbs to mutilated soldiers and seamen. The effect of this law, in bringing to Washington a large number of pensioners to present their claims, has permitted the study of the remote effects of injuries and mutilations. The peculiar value which the surgical data of the late war have acquired in consequence of the measures taken to trace the ulterior results of the more important cases cannot be overestimated. In the reports of the surgery of European wars, and of campaigns in India, Abyssinia and elsewhere, the history of cases terminated when the men were invalided or discharged. Although the elaborate reports of the casualties of the French armies in the Crimean and Italian Wars were published in 1865 and 1869, after an interval of ten years from the conclusion of hostilities in each case, no information is given subsequent to the date of discharge or pension."

"The abstracts of cases in this Office are invariably traced to the date of publication."

It appears, therefore, that we may expect soon to see the first instalment of this valuable work. The publication of the remaining portion depends upon the action of Congress, and we sincerely hope that the necessary authority and means will be granted during the present session.

The only manner in which Congress can judge of the great value and desirability of such a work is by the opinions of professional men upon such samples or extracts from it as have been already published. These are furnished in a memorandum of extracts from letters, reviews, etc., by some of the most prominent men in this country and Europe, which accompanies the Report; and we can assure our legislators that there is no higher tribunal for judgment as to the merits of such work as has been and is proposed to be done, under the direction of the Surgeon-General, than the authors of the letters and reviews above referred to. These gentlemen reflect truly the sentiments of the entire profession of the country.

The reports of sick and wounded furnish the following results:—The average mean strength during the year was 29,022 white, and 3,407 colored troops. Among the white troops 53,836 were taken on the sick report for disease, and 8,744 for wounds and accidents. The number constantly on sick report was 1,419. The total number of deaths reported was 374, —249 from disease, and 125 from wounds and injuries. 745 white soldiers were discharged for disability. Among the colored troops, 5,479 cases of disease, and 729 wounds and injuries are reported. The number constantly on sick report was 178. The number of

deaths was 66,—51 from disease, and 15 from wounds and injuries. 104 colored soldiers were discharged for disability.

The marked difference between the mortality of white and colored troops is an interesting fact meriting full discussion, which we hope it will receive at no distant day.

Ethnologists will be glad to learn that "the collections now include eight hundred and ninety-seven (897) human crania, and thirty-four (34) skeletons. Elaborate tables have been prepared, exhibiting their measurements. The diameters, facial angle, internal capacity, and position of the *foramen magnum* are indicated for each cranium. It is hoped that the publication of this important contribution to anthropological knowledge will be authorized by Congress. The tables, arranged to correspond with those published in the *Crania Americana* of Samuel George Morton, would worthily supplement that great work. The Museum possesses a larger number of skulls from tumuli, and of crania of North American Indians, than are elsewhere collected, and it would appear due to ethnologists throughout the world that descriptions of the specimens should be published, as was done by the Russian Government for the collection of Professor von Baër at St. Petersburg."

We hope that the authority asked for will be granted, for there can be no question as to the desirability of such a publication.

We are sorry to learn that the law stopping appointments and promotions in the Medical Corps is still in force. The number of vacancies at present is 2 surgeons and 46 assistant surgeons.

"The number of Commissioned Medical Officers available for duty with troops on the 30th of June, 1870, was one hundred and forty-seven (147); on leave of absence, four (4); on sick leave, four (4). The estimated number of troops in service at that period was thirty-two thousand four hundred and twenty-nine (32,429). There were two hundred and seventeen (217) military posts, besides numerous detachments serving in the field and on outpost duty, each requiring a medical officer. The number of Commissioned Medical Officers being inadequate, Contract Surgeons are employed, as heretofore; but it would be more economical and satisfactory to be able to fill the existing vacancies in the regular Medical Staff of the Army. So long as our extended frontier exists, with its isolated military posts and moving detachments of troops, so long will the Medical Staff be required to be kept up to the standard number allowed by existing laws, and any reduction of that number will be prejudicial to the best interests of the military service."

Congress should repeal the law, and allow these vacancies to be filled up. It is very bad policy and poor economy to discourage the members of the Medical Staff proper, and to compel the employment of an increased number of men who cannot be required to possess the education and knowledge which is guaranteed by having passed an examination before a regular army board.

There are several other points of interest in this report, but we shall refer to but one, namely, the cost of the Medical Department, which is very much smaller than we had supposed; the current expenses during the year being only a little over 236,000 dollars. We suppose this is due to some extent to the fact that there must have been a large stock of supplies on hand, left over from the war; but when we consider that the number constantly sick was 1,597, giving 582,605 of treatment, and that these men were scattered by twos and threes from Florida to Alaska, it must be admitted that forty cents per day is a very moderate allowance.

A DIFFICULTY between the managers of the Nursery and Child's Hospital of this city and Dr. Jacobi has terminated in the expulsion of the latter by the medical staff. Such a statement sounds strangely to those who know Dr. Jacobi professionally and personally, but the facts upon which the assertion rests are stranger still. It seems that the gentleman in question took occasion in a lecture to some students to speak of the peculiar affections that were to be met with in such institutions, due in a great measure, as in this instance, to their faulty construction, want of ventilation, and other matters well enough appreciated by every physician. These remarks gave offence to the managers, who, by a communication to the Medical Board, requested his resignation. As the constitution provides that all medical affairs shall be in the hands of the staff, it was necessary to commence the action in this way; at the same time the managers threatened, in case the request was not granted, to alter the constitution in such a manner as to give them the power to act under such circumstances of their own accord. Naturally enough, reasons for such a communication are asked by the staff, and a solicitation for specific charges made. A Committee of Conference is appointed, but with no direct result, and the doctor settles the affair for a time by promising to resign in the course of the year, in order that the accusations may have time to appear. After waiting a while he addresses a letter to the managers demanding officially the cause of action. While so doing he answers certain unofficial objections to his course in the institution in a seemingly satisfactory manner. In this letter, in order to protect his position, he denies the truth of some statistics furnished by one of the Medical Board, and published as an official report by order of the managers in one of the daily papers. Nothing comes of this letter, and Dr. Jacobi as an alternative recalls his promise to resign. After a short interval of time the medical staff meet, and while asserting that they had "nothing to do with statistics and charges," declare the place vacant in consequence of insults to the ladies, managers, and

to the Medical Board, the said action being taken "in the interests of the institution."

There is of course always a good deal of personal feeling mixed up with such affairs, but with this we have nothing to do; our concern is with the purely professional aspect of the question. A number of managers are offended at one of the medical staff; they have no power to expel him, but threaten to alter the constitution to permit them so to do in case the staff itself, which has such power, does not. One thing is settled, the obnoxious doctor must give up his place in any event. The managers refuse to give any reasons for the request, either to the Medical Board or to the defendant. Next in the order of events this same Medical Board declare the place vacant "in the interests of the institution," because of insults to the staff and managers, at the same time declaring that they have "nothing to do with statistics or charges." The expressed and unalterable determination of the managers to get rid of Dr. Jacobi may have had nothing to do with the final action of the staff; but it is a strange coincidence to say the least. Any person outside of the profession who imagines that doctors can quarrel and act meanly towards each other, would be apt to link the actions of the managers and those of the staff in the light of cause and effect. But we in charity are content to go as far as the coincidence, and simply regret the circumstances which compelled the staff to expel a member who was foredoomed by the managers. It was a question of time. The managers declared they would alter the constitution to suit the case, why could not the staff be a little patient? By failing to do so, even admitting that their action as regards Dr. Jacobi was just, they have, in the eyes of the managers at least, established a precedent to expel each other when the said managers see fit to bid them.

Whatever view we may take of the respective merits of the case, it is well that the blow fell not on a beginner, who, losing his hospital appointment, loses everything.

THE CARBONATE OF SODA OF THE BIBLE.—Professor Chas. A. Joy (*Jour. of Applied Chemistry*) asserts that in the Bible carbonate of soda is called nitre, from the Greek word *nizo*, meaning to cauterize, to wash. The first use of soda is shown in Jeremiah: "For though thou wash thee with nitre, and take thee much soap," &c., &c. In Proverbs, we learn that Solomon knew what would be the action of acetic acid upon the carbonate of soda, for he says: "As he that taketh away a garment in cold weather, and as vinegar upon nitre, so is he that singeth songs to a heavy heart."

REFRACTION AND ACCOMMODATION.—Dr. G. Hay, of Boston, Mass. (*Boston Med. & Surg. Journal*), asserts that, out of 6,345 eye-patients treated at the Boston Infirmary, there were 394 cases of anomalies of refraction and accommodation; that is, about one in sixteen.

Reviews and Notices of Books.

THE TRANSACTIONS OF THE AMERICAN MEDICAL ASSOCIATION. Instituted 1847. Vol. XXI. Philadelphia.

THE present volume contains as usual the minutes of the last meeting, the address of the President, Dr. George Mendenhall, and the various committee and other reports. In the report on anatomy and surgery we find a paper on median lithotomy, by James L. Little, M.D.; a new operation for imperforate anus, by Thos. M. Healy, M.D.; a paper on neuralgia of the jaw-bones, by S. D. Gross, M.D.; one on partial paralysis from reflex irritation caused by congenital phymosis and adherent prepuce, by Lewis A. Sayre, M.D.; a case of congenital occlusion of the rima glottidis, by Louis Elsberg, M.D.; a new method of reducing dislocations at the shoulder-joint, by Samuel Logan, M.D.; a contribution to plastic surgery, by Gurdon Buck, M.D.; a case of formation of bone in the eye, by C. M. Carleton, M.D.; a new mode of amputation at the ankle-joint, by J. N. Quimby, M.D.; and a new method of lithotrity, by E. M. Moore, M.D. In the report on medical jurisprudence, hygiene, and physiology, the paper on the cellular structure of the red blood-corpuscle, by Dr. Jos. G. Richardson, is one of special interest. Under the same head there is a report on the doctrine of force, by J. H. Waters, M.D. Under climatology and epidemics, Dr. D. Francis Condie reports on the diseases of Pennsylvania for the years 1867-8-9, and Dr. R. C. Hamill on the topography, climatology, and epidemics of the State of Illinois. Under the practice of medicine and obstetrics, Dr. J. Byrne has a paper on intra-uterine injections; Dr. Nathan Allen one on the physiological laws of human increase; and Dr. Thomas Antisell a report on the cultivation of cinchona in the United States. A prize essay on the treatment of aneurism, by Dr. B. Howard, exhibits much patient investigation. Our space will not permit us to do more than refer to the various papers, but many of them will be found of unusual excellence and interest. The thanks of the Association are due to Dr. Wm. B. Atkinson, the Permanent Secretary, for the care and ability with which he has arranged the Transactions for the press.

THE PRACTITIONER: A Monthly Journal of Therapeutics. Edited by FRANCIS E. ANSTIE, M.D., F.R.C.P. Macmillan & Co., London, and 63 Bleecker Street, New York.

THE December number of this excellent and popular journal closes its fourth volume, and those who have been constant readers of the *Practitioner* will agree with us that its popularity is richly merited. Good as it was at the beginning, it has gone on in a steady career of improvement until it has attained the foremost rank in medical literature, laying before the profession every month a series of valuable original communications by men of eminence, critical and discriminating reviews, interesting clinical notes, and a comprehensive summary of intelligence gathered and condensed from the various British and foreign journals. The American reprint of the *Practitioner*, wholly unauthorized as it is, appears to have found little favor, having had nothing to recommend it but a trifling difference in cost—a very insignificant offset against a considerable delay and a much inferior style of typography.

We are pleased to learn from Messrs Macmillan & Co. that henceforth the annual subscription to the English edition will be four dollars instead of five—a reduction justified by the increased number of subscribers, and one which will doubtless be fully appreciated by the profession.

LUNACY: ITS PAST AND PRESENT. By ROBERT GARDINER HILL, F.S.A., Author of the Non-Restraint System of Treatment in Lunacy, Superintendent of the Lincoln Lunatic Asylum, etc. London: Longmans, Green, Reader, & Dyer. 1870.

THIS little volume is an able and emphatic plea for the non-restraint system in the treatment of lunatics. The author gives an appalling picture of the state of lunatic asylums under the system of restraint, with many well authenticated cases of barbarous treatment and its lamentable results. He claims that he has been instrumental in abolishing such brutalities, and in inaugurating a system having for its foundation kindness and humanity.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

STATED MEETING, NOVEMBER 17, 1870.

DR. H. D. BULKLEY, PRESIDENT, in the Chair.

SUBJECT :—*Continuation of the Discussion of Paper on "Pathology of Pulmonary Phthisis," by W. H. Draper, M.D.; and of Paper on Recent Views in Relation to "Pulmonary Tuberculosis," by Austin Flint, Sen., M.D., recently read before the Academy.*

DR. AUSTIN FLINT, Sen., in opening the discussion, remarked as follows:—I have already had my say respecting the subject which is before the Academy, and it would be unbecoming for me to occupy much of the time to be devoted to it this evening. In compliance with your request, however, I will offer a few remarks, by way of reopening the debate.

In the discussion thus far, considerable attention has been directed to the pathological character of the tuberculous products known respectively as granulations and tuberculous infiltration. Great importance seems to be attached by some pathologists to the doctrine that these two products are essentially different. The histological points of difference are deemed sufficient to constitute the anatomical characteristics of different diseases, and diverse names are applied to tuberculous infiltration—the name tubercle being reserved exclusively for the granulations.

I cannot but think that Dr. Leaming is correct in attributing to a prominent advocate of this doctrine an anti-Laennec *animus*. This *animus* seems to pervade the writings emanating from the Berlin school of pathology. Laennec had not the advantage of the microscope. Doubtless he could have availed himself of it had its value then been known; and it is no disparagement to his renown that he did not discover its value in addition to the discovery of auscultation. Laennec, however, in as far as his researches could go, came to a conclusion which his histological opponents now admit, namely, that the true tuberculous products undergo the same kind of metamorphosis, and become after a time identical.

It is plain that discussion will avail but little in settling the question whether these products are primarily so distinct as to constitute different affections. The question can be settled only by facts, histological and clinical. Histological observers are not all agreed as to the teachings of the microscope in relation to this question. An observer, perhaps as able and reliable as any one—Villemin—claims that the tuberculous infiltration is preceded by, and is the result of granulations which, as he thinks, are developed within the air-cells, as well as in the extra-vesiculo-areolar tissue.

It seems to me that in the discussion which has taken place, the fact of the almost constant coexistence of tuberculous infiltration and the granulations has not been sufficiently considered. While it is true that either product may be found without the other, after death, it is undoubtedly true that their association is the rule.

This rule shows an intimate pathological relationship between the two products. Granting that they are, histologically, different products—one a neoplasm, and the other an inflammatory exudation—is it not a fair inference from their constant association, that they are different phases or manifestations of one disease?

At all events, is it not at least premature to say that, when the two products exist together, the patient has two diseases, as when Niemeyer, in the passage from his work which has been repeatedly quoted in this discussion, states the danger in consumption to be the development of tuberculous disease?

There is a form of tuberculous disease which differs in a striking manner from the ordinary form of disease in cases of phthisis. I refer to the accumulation of granulations in great number in the lungs and other organs, without the coexistence of tuberculous infiltration. Considering the febrile phenomena and the shortness of the duration of this form of disease, it is appropriately distinguished by the name acute tuberculosis. Cases of this form of disease are rare. In cases of chronic phthisis, tuberculous infiltration is always present, and on examination after death, granulations are almost invariably found in greater or less number. Whether, in these cases, the granulations precede or follow the tuberculous infiltration, is a question concerning which there is a difference of opinion, some histologists considering the latter as primary, causative of the former, others holding an opposite opinion. Now, I submit that it is not unreasonable to protest against the attempt to supersede the name chronic phthisis or tuberculosis by other names, such as cheesy pneumonia, catarrhal pneumonia, lobular pneumonia, etc.

If we must have the name pneumonia, instead of tuberculous infiltration, it should, as it seems to me, be called tuberculous pneumonia.

At the last meeting of the Academy, Dr. Peters stated that there is nothing very new in the so-called new views in relation to the pathology of pulmonary tuberculosis. This I believe to be a correct statement. If we subject the views just noticed to a critical analysis, it will be found that the novelties are nominal rather than real. The non-identity of the granulations and tuberculous infiltration is not a new doctrine. This was the doctrine of Bayle in 1809. Bayle made the same distinction which is now made between these two products, considering each as representing a distinct species of phthisis; only he limited the name tubercle to the infiltrated or yellow product, calling the disease tuberculous phthisis, and the other species granular phthisis. Here is a normal, not a real, difference. That the infiltrated tuberculous product is the result of an inflammatory process, is a doctrine which has always been maintained by distinguished pathologists. The novelty here consists in this: It is insisted now that the disease represented by this product shall be called a pneumonia, and that it shall not be called a tuberculous disease. Here again is a nominal, not a real, difference.

Is there any practical advantage in these proposed changes as regards names? If by means of new names practical ideas are to be affected, irrespective of the results of clinical experience, then, so far from the changes being useful, they may prove injurious to medical practice.

It is certainly not a legitimate object of a nomencla-

ture to influence thereby opinions. The great object of a nomenclature is obviously convenience, and to this object even propriety and strict accuracy should sometimes be made subservient. I find it difficult to see any good to be effected by calling a tuberculous infiltration a pneumonia. On the other hand, the change begets confusion and embarrassment. The name pneumonia, as applied to any form of pneumonic inflammation, is undesirable, inasmuch as there is an obvious advantage in conforming as far as possible to the terminology which denotes an inflammatory disease.

If it must be that our German brethren compel us to succumb and accept the name pneumonia, let us hope that they will allow us to prefix the adjective tuberculous. It seems to me that we are entitled to this, in view of the relationship between the two products; and also, in view of the fact that the form of disease heretofore known as infiltrated tubercle differs so widely, in its anatomical changes and clinical history, from other affections designated pneumonias.

How unlike chronic phthisis to acute lobar and interstitial pneumonia, as well as to the affection which has been called lobular pneumonia!

The President of the Academy has suggested to me that a topic of importance in the discussion has received but little notice, namely, assuming that the granulations alone constitute tuberculous disease, can their existence be determined, with anything like positiveness, during life, when they are associated with what it is proposed to call tuberculous pneumonia? The importance of this topic is obvious, for of what use is it to consider these different morbid conditions as distinct diseases, associated as they generally are, if it be impossible to determine whether the tuberculous pneumonia exist alone, or whether tubercles are also present? Niemeyer, who thinks that the tubercles are developed consecutively to the pneumonia, endeavors to point out symptoms denoting their occurrence. But this supposed significance of certain symptoms is based wholly on conjecture. How can it be determined, so long as it is an unsettled question, whether the tubercles precede or follow the pneumonia?

To those who agree with Niemeyer in saying that the "greatest danger for the majority of consumptives is, that they are apt to become tuberculous," it is fair to propound the inquiry, is it practicable to determine, clinically, the supervention of tubercles? Will any one, with our present knowledge, undertake to say, at the bedside of a consumptive patient, at one time that tubercles do not exist, and, at another time, that they have been developed?

The assertion, by Niemeyer and others, that bronchial hemorrhage may be a cause of phthisis, has been a topic for remarks at the two last meetings of the Academy. I find myself here not in accord with Dr. Clark and Dr. Leaming respecting one point, namely, the occurrence of hemorrhage when there is no other evidence of a tuberculous affection, and when the hemorrhage is neither vicarious nor referable to disease of the heart.

I have met repeatedly with cases in which, after an attack of hæmoptysis, a careful exploration of the chest revealed no signs of tuberculous disease. If it be said that this result is only evidence of a want of skill in the practice of percussion and auscultation, I answer that in some of these cases years have elapsed and no symptoms of tuberculous disease have occurred. In one of these cases the lungs were examined, *post-mortem*, two years and five months after the date of my examination. I refer now to the case of the late Dr. Southack. Dr. Southack had an attack of hæmoptysis in July, 1867. The day after this attack I examined the chest, and recorded the result, three days afterward, as follows: "On examination of the chest, the only signs found were feebleness of the respiratory murmur in the left infra-clavicular region, and a very slight subcrepitant râle in the same situation. . . . He has had repeated attacks of acute articular rheumatism, but the heart has escaped." He was also examined by Dr. Janeway, who failed to find signs sufficient to denote tuberculous disease.

Dr. Southack died Dec. 14th, 1869, and at the autopsy there was no trace of any tuberculous affection. The weakness of the respiratory murmur at the left summit was accounted for by a depression of the lung caused by the thickening of the pleura.

It was suggested by Dr. Draper, at the last meeting, that a bronchial hemorrhage alone may give rise to signs which may lead to an erroneous diagnosis of tubercle. I can understand that this may be so. The presence of blood in the bronchial tubes, and a local hyperæmia may, perhaps, occasion, in some cases, slight dulness on percussion. Feebleness of the respiratory murmur may be thus produced; and a subcrepitant râle may be present, as it was in the case of Dr. Southack.

As regards bronchial hemorrhage being a cause of tuberculous disease, I agree with Dr. Clark and Dr. Leaming in the denial of the statement by Niemeyer and others. But I do not base my denial on the belief that when a tuberculous affection is found to follow hæmoptysis, the affection always existed at the time of the hemorrhage. On the other hand, I base my denial, 1st, On the occurrence, in a certain proportion of cases, of hemorrhage without being followed by tuberculous disease, or, if the latter follow, it is after too long a period to show any causative connection; 2d, On the fact that hæmoptysis, as a rule, is a salutary event in cases of phthisis. The statistics of Ware have established this fact, and, in my mind, it is corroborated by my own experience.

An important question, which has been considered by those who have participated in the discussion, is, whether bronchial catarrh or bronchitis leads to the common form of phthisis, namely, tuberculous infiltration, as affirmed by Niemeyer and others? This question is to be settled, not by reasoning, but by facts. It is to be settled by clinical facts. The autopsical appearances are not adequate to settle it. These appearances show bronchial inflammation, for bronchitis is a constant concomitant; but we do not learn by the scalpel whether the bronchitis was primary or secondary, and the answer to the question hinges on this point. Louis, in his researches on phthisis, published nearly fifty years ago, reached the conclusion that the development of phthisis is rarely preceded by bronchitis. It is a hazardous undertaking to theorize or reason against the conclusions based by this admirable observer upon an analysis of recorded cases. As regards the relation of bronchitis to phthisis, I will venture a stronger statement than belief, and say that I *know* he is right in his conclusions.

It is an exception to the rule, when a tuberculous affection follows immediately upon a bronchitis. I say this after having recently made abstracts of several hundred cases of phthisis which I have recorded during the last thirty years. So firmly convinced am I of the correctness of this statement, that, whenever I am satisfied, from a physical examination of the chest, of the existence of a bronchitis only, I am accustomed to assure patients that they are no more liable to consumption than if the bronchitis did not exist. The facts relating to this, and various other points of inquiry which an analysis of my cases may develop.

I propose, if life be spared, to submit to the profession.

With regard to this point, the considerations presented by Dr. Leaming are cogent, namely, that phthisis rarely occurs in connection with the bronchitis associated with disease of the heart; that patients with long-standing bronchitis which has led to emphysema, as is well known, seldom become tuberculous, and that among children who are prone to bronchitis consumption is rare.

To these considerations another may be added: Phthisis occurs after measles sufficiently often to show a connective relation; but, as a rule, phthisis is not developed until weeks or months after the bronchitis, which is an element of measles, has disappeared.

In conclusion, there are important questions connected with the pathology of tubercle which have as yet entered very little into the discussion. I refer to the bearing of pathological views upon the treatment. They who insist that in certain cases of phthisis the disease shall be called a pneumonia, and that the pneumonic inflammation is often the effect of a bronchial catarrh or a cold, which has been either neglected or badly treated, advocate a return to therapeutical measures which within late years have become almost obsolete. Is it wise to go back to blood-letting and confinement within doors, and even to the bed, in the treatment of phthisis?

This is a question the importance of which is so great that it should not be overlooked or ignored in this discussion. As I have already, in these opening remarks, occupied a longer time than I had intended, I will only say with reference to the question, that to answer it affirmatively is to disregard the lessons of experience, a renewal of which, I cannot but think, would involve shortening of life and an increased mortality among the hosts of phthisical patients.

Dr. E. R. Peaslee said that he had listened to these papers and discussions with a good deal of interest, and although he had not intended to take any part in the discussion, he felt that certain points had not been fairly put, and he would, therefore, say a few words in defence of Niemeyer and his views. The difference between Niemeyer and Laennec is one of terms rather than facts, or theory. Laennec described phthisis as a constitutional disease characterized by two forms of matter, both of which he called tubercle—one the miliary tubercle, a gray, semi-transparent substance, the other a yellow, opaque, cheesy substance, a later development, as he believed, of the former.

Niemeyer also finds two kinds of matter, the gray and the yellow, but calls only one of them, the former, tuberculous. He does not say that tubercular infiltration is pneumonia; but that this yellowish, opaque matter is not tubercular, but caseous matter. Now casein is an element of milk, and the term caseous matter means simply a matter like casein, or cheesy. It may or may not be formed from casein, and it makes no difference whether it contains casein or not. Laennec was consistent when he found two kinds of matter, and called them both tubercular. Niemeyer is not consistent in saying that one of them is not tubercular, and yet calling the disease in which it is found phthisis. We should not call a disease in which there are no tubercles phthisis; and yet it is easy to understand Niemeyer, who maintains that though these patients are not tubercular, they will probably become so. Infiltration in the lungs will produce caseous matter more readily than in any other part of the body. It is a descending metamorphosis, hastened by the exudation being exposed more directly to the atmosphere than in other tissues.

Niemeyer also states that though there are the two kinds of matter, the miliary and the yellow, the exudation of pneumonia may be converted into the latter, and if tubercles are now developed the danger is very much increased; and hence, if one gets pneumonic phthisis, he will also get tubercular phthisis. His error is in calling the former phthisis; and with this exception we can agree with him.

The speaker does not accept the assertion that pneumorrhagia or hæmoptysis produces tubercles, but it may produce caseous matter if there be inflammation that is neither relieved by the bleeding nor terminates in resolution, for we shall then have infiltration, and then caseous, and finally tubercular phthisis. Niemeyer overrates the importance of his discovery in believing that it will lead to a more prompt treatment of pneumonia with a view of preventing the final development of tubercles, for in the treatment of pneumonia we always aim at arresting the progress of the disease as soon as possible. He has called attention to the fact that yellow tubercle has no distinctive feature on which to base a diagnosis. Dr. P. thinks we should not call this tubercle.

On motion, the Academy adjourned.

Stated Meeting, Dec. 1, 1870.

Dr. H. D. Bulkley, President, in the Chair.

The reading of the Annual Reports followed. Dr. Pond, the Treasurer, suggested, from the prosperous state of the finances, the appropriation of five hundred dollars to the building fund. On motion of Dr. Post this was carried. The building fund, including this appropriation, now amounts to $11,952.12.

The Report of the Recording Secretary exhibited an increasing interest in the meetings of the Society by its members. Nineteen stated meetings were held during the past year, and ten papers read, followed by profitable discussions.

The Corresponding Secretary, in his Report, alluded to the death of an Honorary Fellow, Dr. William Gibson, of Philadelphia, who died last summer in Newport, R. I.; also the death of a Corresponding Fellow, Sir James Y. Simpson, M.D., of Edinburgh.

The total membership of the Academy amounts to 313; of which 283 are Resident Fellows; Non-resident Fellows, 4; Corresponding Fellows, 23; and Honorary Fellows, 3.

Two hundred and eighty-six books and pamphlets were donated to the Academy within the fiscal year, and have been added to the library. Nineteen new members were admitted during the year.

Nominations were then made for officers for the ensuing year, to be elected on the first Thursday in January. Dr. H. D. Bulkley was renominated for President, but declined, stating that he was in favor of rotation in office. Drs. Isaac E. Taylor, E. R. Peaslee, A. Underhill, A. C. Post, and W. Detmold were the candidates for the Presidency. Numerous candidates were named for Vice-President, Recording Secretary, Corresponding Secretary, Treasurer, etc.

The President stated that there would be no annual oration this year, on account of the illness of the appointed orator, Dr. R. Cresson Stiles.

Dr. W. F. Thoms was appointed the biographer of the late James Hyslop, M.D.

Dr. Stuyvesant F. Morris was elected by ballot a Resident Fellow.

Dr. S. Fleet Speir, of Brooklyn, exhibited a new *artery-constrictor*, for the occlusion of arteries without

a ligature, having a flattened tube, through which passes a steel rod, with a hook at the distal end and a screw at the proximal extremity. He has not only successfully experimented on the horse and dog, but has applied the instrument to the profunda and femoral arteries of a female in a case of amputation.

The following novel instruments were also shown by the speaker: A *bivalve ear-speculum*, self-retaining, and requiring no special illumination; a *lachrymal catheter*, shaped like a lachrymal sound.

In answer to Dr. Garrish, as to the time required for the application of the artery-constrictor, Dr. Speir replied that in his experiment on the carotid artery of the horse the instrument was retained at the distal extremity one minute and thirteen seconds, and at the cardiac extremity one minute. He also stated that he had not tried it in aneurism.

The "Continuation of Discussion of Papers of Drs. W. H. Draper and Austin Flint, Sen.," being then in order, Dr. Alfred L. Loomis read the following interesting paper on Pathology of Pulmonary Phthisis:—

Mr. President—The unsettled state of the pathology of pulmonary phthisis has allowed a wide range to this discussion.

When the subject was first announced, it seemed to me that a long series of investigations, experiments, and observations must be made before one could be prepared to enter on its discussion, and that it was impossible for one in a few weeks to prepare himself to speak more than intelligently upon it.

So far as I am able to understand and comprehend the statements that have been made, no new material has been added, and no new facts brought forward that tend to settle disputed points.

The discussion has assumed somewhat of a partisan character. On the one hand, Niemeyer's phthisis has been assailed; on the other, Laennec's tuberculosis. As I understand it, Niemeyer has no claim to originality in the views of phthisis found in his Practice of Medicine; they are simply a compilation of the views of the German pathologists on this subject. The question that comes before us then is, Shall we accept the German pathology of pulmonary phthisis, or retain the hitherto accepted doctrine of pulmonary tuberculosis? This question cannot be satisfactorily answered by the mere opinions of medical observers, unless such opinions are sustained by an accumulation of facts. Theories, it seems to me, do not advance medical science; certainly they can have but little weight in deciding a question like the one before us.

Personally I am inclined to accept the German pathology of phthisis, for it tallies best with my clinical and dead-house experience; yet I have few facts to sustain me in this opinion,—it is rather an impression, the result of general observation, always an uncertain guide.

As a text on which to base the few words I have to say, I will read a summary of cases observed at the Bellevue Hospital post-mortem room, from May, 1868, to December, 1869, as prepared by Dr. Edward Janeway. During this period 400 post-mortem examinations were made; phthisis in its different varieties was found in 63 cases. The summary of these cases is as follows:—

Gray tubercles only were found in 5 cases.
Lobular pneumonia only was found in 12 "
Fibrous induration only was found in 5 "
Lobular pneumonia and gray tubercles were found in 7 cases.
Lobular pneumonia, gray tubercles, and fibrous induration in 19 cases.
Lobular pneumonia and fibrous induration only in 12 cases.
Gray tubercles and fibrous induration were found in 2 cases.
Lobular pneumonia, with gray tubercles of pleura, was found in 1 case.

Cavities in the lungs were present in 38 of these cases.

General tuberculosis in 4 cases.
Tubercles of the pia mater in 4 cases.
" " liver " 3 "
" " peritoneum " 4 "
" " spleen " 3 "

In 29 of these 63 cases, no tubercles were found. They were confined to the lungs, with but five or six exceptions.

In 50 of the 63 cases lobular pneumonias were found.

Fibrous induration was marked in 34 of the cases.

Cheesy pneumonia and fibrous induration constituted the main pathological lesions in all except the cases of general tuberculosis.

The histories of the cases of general tuberculosis furnish some points of especial interest. I will read them in full.

The first was a male child who died of tubercular meningitis. The air-passages to the lungs and the thymus gland were normal. The bronchial glands were enlarged. They contained a few gray and white tubercles, but were for the most part in a state of softening, containing a puriform fluid. The lungs, with the exception of the lower lobe of right lung, appeared normal.

In that portion near the root were a few gray tubercles, and the surrounding lung-tissue was partly in a state of red hepatization, partly compressed by an enlarged bronchial gland in a softened condition.

The liver contained a number of tubercles.

The cortical portion of the kidney contained a number of tubercles. No other tubercles were found, nor other lesion, beyond slight enlargement of the solitary glands and Peyer's patches in the intestinal canal. If one assumes that tubercles originate as a result of some cheesy matter or other process, in this case enlargement and softening of the bronchial glands may have served as a focus for the disease.

Case 2d. Michael M'Affry, aged 40. *Autopsy*, December 28th, 1869. *Tuberculosis of pia mater.* There were tubercles of the pleura and lung.

The right upper lobe contained a few small cavities with purulent contents. The middle lobe was in a state of cheesy hepatization.

Nearly the whole of the left lower lobe was in a state of red hepatization. There were tubercles scattered throughout all the lobes of the lungs; some of these were gray and transparent, others opaque and white.

In the substance of the liver and on its capsule were a few tubercles. The surface of capsule of the spleen was studded with tubercles. One of the calyces of the left kidney was blocked up by cheesy matter, partly disintegrated, and by the thickening of its walls. In several of the other calyces gray tubercles were found, and in the mucous membrane of the pelvis three small yellow masses the size of one half a split pea. The right kidney contained none. There were also tubercles of the peritoneum, omentum, and mesentery. The choroid, bladder, seminal vessels, prostate, larynx, and trachea contained no tubercles.

In this case the tuberculosis might have originated from two foci, viz., from the right lung or else from the kidney. But the process at the apex of the right lung was apparently the older, and hence, with the assumption of a local origin, was the starting-point of the disease.

Case 3d, Occurred in male, 48 years old. *Autopsy*, February 9th, 1869.

There were tubercles of the pia mater, with but few evidences of meningitis.

The right pleural cavity was the seat of pneumothorax. In the upper lobe of the right lung there were two cavities containing pus and cheesy matter. In the lower lobe was a cavity which had opened into the pleura. In the left lung there was a small cavity at the apex and base surrounded by cheesy tissue. Throughout the rest of this lung small lobular cheesy pneumonias were found. At the apex these were aggregated and surrounded by red hepatization; at the base they were surrounded by congested lung-tissue. No tubercles were found in any other organ than the pia mater. In this case the cheesy masses in the lung may have been the focus whence the tubercles of the pia mater originated.

Case 4th, Was one of general tuberculosis in a male child, eight months old, born in the Hospital. Was plump and well till two months before his death. The child was nursed by the women in the ward promiscuously,—his mother having had puerperal mania, followed by synovitis of the wrist and knee-joint. The child gradually failed in flesh and strength, without diarrhœa. Two weeks preceding had convulsions. Gray tubercles were found throughout both lungs. Tubercles were found beneath the pericardium in the connective tissue. Gray tubercles on the surface of the intestines. Miliary tubercles in the cortex and pyramids of the kidneys. There were numerous ulcerations in the small and large intestine. Peyer's patches enlarged and ulcerated over great part of their surface. Tubercles found also in mesentery, omentum, pleura, and in the choroid of each eye. The mesenteric glands were enlarged and cheesy. *No disease elsewhere.*

In this case the question of the origin of the tuberculosis is one of some delicacy.

Apparently the starting-point of this disease was in the intestinal canal, and was a simple follicular ulceration at the outset, followed by hyperplasia of the mesenteric glands, and later by cheesy degeneration of their contents. If so, the focus of the disease was readily found. It was evident that the lesion in that locality was of the oldest date. It may be objected that the child had no diarrhœa, yet diarrhœa is not an essential of ulceration of the intestinal glands, as is often seen in typhoid fever. These four cases are certainly sufficient to show the frequency with which some lesion is found to precede tuberculosis, and that lesion one in which cheesy degeneration is found. The question of the origin of tuberculosis is far from being settled. Yet it seems to me that in some cases it undoubtedly has its origin in a previous cheesy degeneration, a probable embolismic process.

Experiments made by Voldenberg and others on animals would lead one to believe that other particles of matter besides shrivelled cells and fragments of cells might operate in the same way as foci. In all the cases of tuberculosis which have come under my observation recently, some point in the body has been found where processes were in operation which might have served as foci for the disease.

The following case will serve to show the difficulties which sometimes attend the search. A young male adult was the subject of a coroner's inquest at the Bellevue Hospital dead-house. He had died in the hospital without a history. He had general tuberculosis; the pia mater, lungs, liver, and spleen, were the seat of its development. I examined carefully for some point which might have served as place of origin, but unsuccessfully, till noticing a piece of red flannel on one knee I opened it, and discovered an old abscess with cheesy contents in the head of the tibia, and partial anchylosis of the knee-joint, with other evidences of a previous arthritis. But for the flannel I should probably have said, this was a case in which general tuberculosis occurred with no originating focus; and those who affirm that in certain cases no such point was discoverable, and hence would wish to entirely break the relationship between the two, do violence to facts on which we cannot as yet speak positively. Nor is it certain in cases reported as containing no point from which the tuberculosis could originate, that such was really the fact; because to do so would imply that every bone and gland and joint had been opened, a thing which is not done. Almost every case of true miliary tuberculosis in the adult that has occurred in Bellevue for the past two years was not recognized as such during life. The diagnosis in some instances was typhoid fever. It seems to me that what is generally understood as pulmonary phthisis is made up of many different lesions, viz., lobar, lobular, and vesicular pneumonias undergoing cheesy degeneration, with fibrous induration of the lung, chronic bronchitis, and lesions resulting from it in the parenchyma of the lung, with or without tuberculosis of the lung or other parts. All these different processes are sometimes met with in the same lung. The starting-point in the majority of these processes is either bronchitis or pneumonic inflammation. During the past two years my clinical studies of phthisis, as much as my post-mortem observations, have tended to convince me that chronic phthisis in the majority of instances is non-tubercular, and that the so-called hereditary or acquired tubercular diathesis is nothing more than a vice of constitution, either hereditary or acquired, which predisposes to degenerative inflammatory processes, and that when this class of subjects are the victims of bronchial or pneumonic inflammations, the tendency is to abundant cell formations and consequent cheesy metamorphosis.

I have a single word concerning physical signs. The recognised physical signs of the first stage of the phthisis are based on inflammatory process. Laennec even says that miliary tubercles furnish no appreciable signs of their presence, and Walsh states that induration rather than tubercle is the cause of the physical signs during the first stage of phthisis. So that by our physical signs we recognize the bronchial and pneumonic process in phthisis, and not the tubercular. There is one fact, or rather observation, which goes far to convince me of the bronchial or catarrhal origin of phthisis. In no instance since I have commenced particularly to investigate this point, have I failed at some point in a suspected locality to hear bronchial râles. A slight depression under a clavicle, loss of expansive movement, slight raise in the pitch of the percussion sound, a rude inspiratory murmur, and a prolonged expiration, to be a physical evidence of incipient phthisis must, I believe, be accompanied either by bronchial râles or evidences of bronchial changes.

NEW YORK MEDICAL JOURNAL ASSOCIATION.

STATED REUNION, NOVEMBER 4, 1870.

DR. ISAAC E. TAYLOR, PRESIDENT, in the Chair.

EFFECT OF OXYGEN ON THE PULSE.

DR. ANDREW H. SMITH read a paper on *The Effect of Inhalations of Oxygen upon the Pulse*, illustrated by sphygmographic tracings. It appears in our present issue. In response to questions at the conclusion of

the paper, the Doctor stated that those cases in which the frequency of the pulse was not reduced by the inhalation seemed to derive no benefit from it; but the cases were comparatively few in which such a reduction was not effected after the treatment had been kept up for a short time; the frequency was reduced in about seventy per cent. of the cases. Some cases of phthisis were very materially improved by the oxygen treatment; in others no improvement was perceptible. In croup, his experience with this treatment had not been flattering, probably because most of the cases were at the last gasp when he had been called in.

Dr. Jerome C. Smith.—Early in Dr. Smith's investigations I was impressed with the value of oxygen as a remedy in certain affections, and I have followed his experiments with great interest, taking many of my cases to him for observation and treatment. My first impressions of the therapeutic importance of oxygen have been fully confirmed, and I may be allowed to refer to a few examples of its efficacy.

One case in particular, although it has been published in the Medical Record [Vol. iv., p. 171], I will speak of very briefly. A child, two and a half years old, having measles, was seized with congestion of the lungs, and was in imminent danger. Dr. Little was called in and told the parents that the child was dying; but, contrary to all expectation, three or four hours later it was still just alive. I then suggested the administration of oxygen; it was given with marked effect, and the child lived.

Last winter a patient in whom I took the deepest interest was suffering from pelvic abscess and a state of extreme nervous prostration, after the operation of ovariotomy. By the advice of several physicians I administered chloral hydrate. She had taken something over two hundred grains in all, when decided symptoms of poisoning, similar to those of belladonna-poisoning, came on. The face was livid—of a perfect mahogany hue—the lividity already giving place to spots of whitening about the nose. Her condition was most alarming; I sent for Dr. Thomas, but he could not be found; then I called in Dr. Purdy and Dr. Andrew Smith, who at my suggestion gave oxygen. The immediate improvement was great; but when the gas was let up for a short time, the grave symptoms returned. The pulse, temperature, and other signs were carefully noted, and it was a matter of demonstration to all of us that the oxygen was the only thing we could rely upon to keep the patient alive. It served to bridge over the chasm of imminent danger.

In a case which more recently came under my notice, the physician had inadvertently administered, to a gentleman suffering from a violent attack of colic, too large a dose of Squibb's cholera mixture, which contains opium and chloroform. The patient had become deeply narcotized, and I was sent for in haste, across the river, to see him. I found his respirations less than five in the minute; to make them count five you must begin with an inspiration and end with one just drawn. He was not totally unconscious; we could arouse him somewhat, telling him "Don't forget your breathing," when he would make an effort and respire for two or three times more rapidly, then lapse into the slow breathing again. This condition lasted for twelve hours, almost without improvement, except while he was under the immediate influence of oxygen, which was given, about four gallons at a time, every half hour or so. Then he could be made to understand that he was in peril, and would exert himself to inhale the gas, and his condition would improve for a while. We did what we could with strong coffee, stimulating enemata, walking him about, and the other ordinary remedies for opium-poisoning; but the oxygen gave the greatest relief, and became our main reliance.

I might go on and relate many cases from my experience with this agent, proving its inestimable value, but will mention only one more. A young woman, supposing herself within two or three days of confinement, applied to me with complete anasarca, urine highly albuminous, almost solidified by heat, and uræmic symptoms so urgent that I felt the necessity of resorting to something beyond the ordinary measures. So, besides the cupping, hot-air bath, etc., we put the patient upon oxygen-inhalation, thinking the gas might act not only to sustain the patient's powers, but also as an eliminant to remove the poisonous principles in the form of urea from the blood. Confinement did not occur as soon as she had expected, and the gravest apprehension was felt for her safety. The danger was safely passed, however; and although it is impossible to say just how much the oxygen-treatment had to do with this, yet it seemed to us, who were watching the case, that something of the success was to be attributed to the eliminating power just mentioned.

Dr. Neftel.—I wish to express my appreciation of the value of Dr. Smith's researches. A glance at a few of the more recently established facts in physiology may explain some of the effects of oxygen-inhalation in certain cases, and its failure to produce any effect in others. Important and all-pervading as are the processes of oxidation in the animal economy—giving origin to heat, electricity, muscular power; liberating and rendering active in the animal system those forces which in the plant had been rendered latent by the opposite process of reduction—yet all these processes are under the control of the nervous centres. Respiration itself, with its complex mechanism of co-ordinated muscular movements, is, as we all know, under the control of the respiratory centre in the medulla oblongata, which, excited, increases the respiratory movements; destroyed or paralyzed, abolishes them. The normal stimulus of this centre is the carbonic acid in the blood; the more of this, the more violent are the respiratory efforts; the less of it and the more oxygen, the less frequent and intense they become, until, when the blood is saturated with oxygen, there is complete cessation of respiratory action, or the condition known as "apnœa" (to be distinguished from the opposite condition of dyspnœa). It is impossible, therefore, to introduce into the system more oxygen than it needs, because this condition of apnœa comes in to put a stop to respiration.

Moreover, the blood itself can absorb only a certain amount of oxygen, determined by physiological and physical laws. We speak of the blood, for, though all the tissues absorb oxygen, yet the chief agents in this are the red corpuscles, which hold it in loose combination with their hæmaglobin. These can receive only a fixed amount, which cannot be exceeded, though we place the animal in an atmosphere of pure oxygen. Again, in certain diseased conditions, the usual amount of oxygen cannot be absorbed—in leuchæmia, for example, where the red corpuscles are deficient in number, or in diabetes, where they are deficient in absorbent power. We know that carbonic oxide has such a strong affinity for the hæmaglobin that it will expel all the oxygen from the corpuscles, and then, no matter how much oxygen we supply, they cannot again absorb it. A patient poisoned with carbonic oxide may die, then, of asphyxia in an atmosphere of oxygen, just as a man may die of starvation with plenty of food before him and a stricture of the œsophagus. When asphyxia is due, therefore, not to want of air in the lungs, but to a diseased condition of the nervous

system or of the blood, we may expect little benefit from the administration of oxygen.

There are other conditions, however, where its use is of the greatest importance, and some which have not been mentioned to-night. It has been satisfactorily proved, in a series of remarkable experiments, that when the system is saturated with oxygen, to the extent of producing apnœa, the reflex irritability of the spinal cord is totally abolished. Animals poisoned with strychnia, and then kept in the condition of apnœa by artificial respiration, have no convulsions. It is an established fact that artificial respiration will prevent or cure convulsions dependent upon reflex irritability of the cord. For this pure oxygen is not required; atmospheric air will serve.

Dr. Peaslee.—This matter of inhaling oxygen as a remedial agent is by no means a new thing. It was practised some sixty or seventy years ago by Dr. Beddoes, and given up because it was impossible to obtain oxygen in sufficient quantity and purity. Now we have not this difficulty to contend with. You know there is a man in Broadway, between Twenty-second and Twenty-third streets, who furnishes the pure gas in cylinders under strong pressure, in a form as convenient for administration as could be desired. We are now, therefore, placed in a position to ascertain precisely what are the effects of oxygen in its therapeutic application.

I rose to say that there are other conditions, besides those we have heard mentioned, where oxygen will enable us to "bridge over the chasm" for the time being. Take a case which came under my notice quite lately. An aged lady, who had been suffering from a disease of the heart for some two years, had a sudden attack of dyspnœa, and sent for me in the night. I sent Dr. Janvrin in my place, and he found her in the utmost distress, with œdema of both lungs. It occurred to him to use this remedy, and he at once obtained a cylinder. About five gallons were drawn off at once, and taken in the course of five or ten minutes, as the case might be, very soon the dyspnœa was relieved, the lividity of the lips disappeared, and the patient was comparatively comfortable. But there was no arrest of the pulmonary œdema. The fluid kept on rising higher and higher, the patient sitting erect. This was at ten o'clock in the morning. The oxygen would relieve her most urgent symptoms for the time, and then she would relapse. The whole day was occupied in giving the gas and keeping her alive, as in my opinion it unquestionably did, until the medicine which had been given for the pulmonary œdema should have time to operate, which it did about dusk, with marked benefit. I do not believe she could have lived two hours without the oxygen, its effect was so apparent in changing the color, diminishing the frequency of the pulse, and increasing its force. Still the cardiac disease was not removed, and the next day the patient had a relapse; oxygen was again resorted to; and so on from day to day for about ten days, at the end of which she seemed to be out of danger for the time. Suddenly, however, symptoms of double pneumonia set in, and she died very speedily. In that case some two thousand gallons of the gas were used in ten days.

I have used it recently, also, in a case of extreme nervous debility, with sleeplessness and rapid irritable pulse, for which chloral hydrate had been given with some benefit. I tried oxygen, and the pulse fell from ninety or one hundred to seventy-two or three; it became stronger as well as less frequent; the appetite improved; and the patient is evidently decidedly benefited.

I think this remedy, properly given and in sufficient quantity—for now we need not stint the patient—will be found of the greatest value in just that way—to "bridge over a chasm." And even in cases where the patient must die in a few days, it can at least prolong life. In the case I first mentioned, the lady knew her condition perfectly, and was very anxious to live until her son and daughter could return from the west, which would take perhaps forty-eight hours. I do not think it was this hope alone, but am convinced it was chiefly the oxygen which enabled her to realize her desire. I am very glad that Dr. Smith has brought this subject before us, and I think we shall all learn to realize its importance within the year to come in the saving of many lives.

Dr. Jerome C. Smith.—It occurred to me, a few days ago, that the gas might be of service in a case of lead-paralysis. Having had painters in my house for about two months last summer, I became through them acquainted with a number of cases of lead-poisoning. Last week, one came to me from Hyde Park, with severe lead symptoms—paralysis of a large number of the muscles of the body, and most obstinate constipation. He had been treated, but without relief; had taken immense quantities of castor-oil, till it would no longer be retained by the stomach; a considerable amount of croton-oil; and, indeed, had gone through the catalogue of cathartics. I found him complaining of very great weight of the limbs, especially the arms, of pain in the abdomen, and of paralysis affecting almost the whole body. He had taken iodide of potassium. I gave it again with extract of senna, and determined to try also the effect of oxygen. He was sent to the office in Broadway, and ordered to inhale the gas for twenty or thirty minutes twice a day. His symptoms were not much relieved for twenty-four hours; and, as he had been very sleepless, I gave him the first night a moderate dose of chloral hydrate, which secured a comfortable night's rest. The second night I repeated the dose with the same result. On the third day he got two drops of croton oil. By the ordinary treatment, coupled with the oxygen, he is now completely relieved. Though we cannot say just how much good the oxygen may have done, yet it is my belief that it assisted very greatly; that, to say the least, it put the patient in a condition favorable to the action of the other medicines. I think that we shall find similar benefit from it in many cases where at first we might hardly expect it to be of much service; that its tonic influence upon the system will render it a powerful adjuvant to the treatment specially directed against the diseased condition.

Dr. Janvrin.—I would say a word on the tonic effect of the gas, to which the last speaker has referred. During the past three or four months I have been experimenting with it somewhat, both in conjunction with Dr. Smith and by myself. I have used it in a great many cases of phthisis, and with benefit in almost every case. The frequency of the pulse would be diminished, and its force increased. I have also employed it in cases of uterine disease, especially where there was marked anæmia. I have one under treatment now—a lady who had come from the south to be under Dr. Peaslee's care; he was away, and she fell into my hands. She was very much emaciated; during the last two years had had seven miscarriages; was suffering from menorrhagia and uterine neuralgia. I gave iron-by-hydrogen, bitter tonics, and local stimulants, but was unable to excite any appetite whatever. She could barely take two or three teaspoonfuls of beef-tea at a time, and even that was almost always rejected by the stomach. It oc-

curred to me that I might stimulate the appetite by oxygen. I gave five gallons twice a day; on the second day she began to show some little appetite, and it has regularly increased.

To Dr. Peaslee's account of the case of œdema of the lungs, I might add that the patient was in a condition of stupor during almost the whole of the first day, the medicine not operating until late at night. Whenever the oxygen was given, it would arouse her from the stupor within five minutes from the time of its inhalation. It was kept up for the ten days. After the pneumonia set in, it was given for three days, and enabled her to converse with her family up to ten minutes before death.

Dr. Gurdon Buck now presented some interesting cases of *Cheiloplasty*, with remarks upon his mode of operating, the report of which is crowded out of our present number.

The meeting adjourned.

New Instruments.

A SURFACE-THERMOMETER.

By E. SEGUIN, M.D.,

NEW YORK.

When thermometry was first introduced in our hospital and private practice, I published in the New York Medical Record, in its No. of January 1st, 1867, an exhaustive article on the subject, accompanied with large diagrams, in which will be found the following prediction: "The *Fever-thermometer* answers very well to measure the temperature of the body taken at completely sheltered places; but we must acknowledge that it is not fitted to measure the abnormal temperature of local inflammation upon open surfaces. It would be often desirable that an excess of local heat might be compared at its different stages with the normal heat of surrounding healthy parts; and we do not doubt that some mechanical genius will yet devise a kind of thermometer whose broad yielding bulb shall adapt itself to any surface of the body, at the same time that its superstructure shall be isolated from atmospheric influence. *What mankind needs man finds.*"

This appeal, exactly four years old now, seems to have been answered by the writer himself, who has just presented the wished-for instrument to the New York Medical Journal Association, as the result of his study and of the ingenuity of Mr. Stohlman, the instrument manufacturer, who tenders so willingly his mechanical skill to the service of medical and surgical inventors.

The question at issue may be thus summed up.

A Fever-Thermometer for General Thermometry.

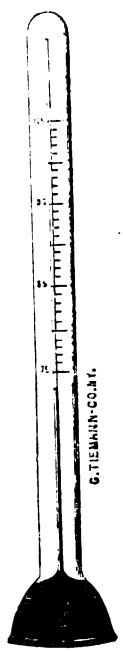
A Surface-Thermometer for Localized Thermometry.

This double proposition needs only a short commentary.

The *Fever-thermometer*, though of recent origin, has already rendered many services. But its shape, well adapted to cavities, does not suit surfaces. How could it be rendered serviceable upon surfaces by some simple and ready modification, remained a desideratum. Hence the necessity arose of contriving a *Surface-thermometer*, whose sensitiveness to caloric concentrated at the bottom of the mercury-reservoir could indicate the exact temperature of any given surface.

The principle of the *Fever-thermometer* is that its standard of health is invariably, according to Wunderlich, 98 6-10 Fahr., from which point it starts up to mark fever, and down to mark devitalization.

On the contrary, the *Surface-thermometer*, acting on surfaces whose temperature depends on a large range of atmospheric and physiologic or pathologic combinations, will mark only the difference of temperature between a well and a sick side or part without a prefixed standard. Hence the necessity, when using the later instrument, to apply it alternately to the part known or suspected to be diseased and to an opposite or neighboring part whose health is unquestionable; so that the difference of temperature found expresses in figures the intensity of the disease: *that* is the standard of the *Surface-thermometer*.



Its structure is sufficiently described by the accompanying drawing, which is full-sized, in all particulars but one that experience will soon settle—that is the rigidity or flexibility of the mercury-reservoir.

Its *modus operandi* consists in warming it in the hand up to 75° Fahr., and placing it at right angles alternately for a few minutes on the two antithetical points selected for the observation. It is useless to remark that, if the sufferer from a local affection is also the subject of general inflammation, he falls under the index of the *fever-thermometer*.

To mention a few cases where the *surface-thermometer* can be used, besides its application in experiments of physiology and organic chemistry.

A.—To measure the power of calorification of localized electricity, of the Mayor's hammer, calorific mixtures, &c.

B.—In the obscure beginnings of hemiplegia and paraplegia it shows a larger evolution of heat on the threatened parts than on the sound ones, and in confirmed paralysis the reverse obtains, the temperature of the affected parts being shown lower than that of those remaining sound.

C.—In articular rheumatism, sciatica, facial neuralgias, &c., the *surface-thermometer* will show rises and falls of local temperature, which may throw a new light on the origins of neuroses.

D.—In local diseases of children, idiots, insanes, and of other persons who cannot indicate the seat of their affection, the *surface-thermometer* may point it out.

E.—With a slight modification in the shape of the bulb, as already suggested by Dr. H. Shiff, or in its present form, not objected to by Dr. Knapp, it will mark the changeable differences of temperature between a sick and a well eye, and may warn of the approach of sympathetic ophthalmia and other accidents. Other specialists will likely find its application to their favorite pursuits.

F.—In the formative stage of deep-seated abscesses, their centre will often betray itself by a higher temperature. In chronic and cold abcesses it will not be so, and may be the reverse.

G.—In deep-seated surgical lesions, the new instrument will often reveal the very centre of disorganization, or the extent of effusions, of which even a skilful hand may remain in doubt. When, according to the energetic expression of John Hilton: * "A surgeon

* "Influence of Mechanical and Physiological Rest in the Treatment of Accidental and Surgical Diseases."

finds himself between two alternatives, "plunge in the knife," or "wait till the abscess comes nearer to the surface; but the patient may die in the mean while," then the *surface-thermometer* will rise higher at the centre of a tumor, even if there is abscess, or fluctuating like the sphygmometer of Jules Herrisson, if there is aneurism: that may prove to be one advantage of the flexible bulb.

H.—The proposed instrument will be in frequent requisition to ascertain the rise or fall of temperature in a region lately submitted to a grave operation, or hidden from view by an immovable apparatus.

I.—The *surface-thermometer* may be equally sensitive to the local evolution of pathological heat in pneumonia, pleurisy, peritonitis, typhoid fever, &c., as in the slower affections, chronic meningitis, pulmonary phthisis, tabes mesenterica, chronic metritis and ovaritis, &c., &c.

Let us observe, moreover, that the mode of investigation instituted by the *surface-thermometer* is kind, and never presents the very grave dangers feared from deep palpations, percussion, succussion, and other often unmercifully repeated manipulations.

In any case the *surface-thermometer* will have also upon the hand, even the hand gifted with the *tactus eruditus*, the advantage of being early brought to a mean, known and impartial temperature; whereas the hand comes to the work of diagnosis with a variable warmth of its own, variously estimated, and variously interfering with the perception of the temperature of the parts under observation.

It is not necessary to dwell any longer upon the advantages of this new and desirable instrument of *positive diagnosis*. It is offered to the profession to be tried; if found imperfect, somebody will perfect it. But in its present shape, or with some happy modification, sooner or later it will be the mate and complement of the *fever-thermometer* in the pocket-case of every industrious practitioner.

ARMY AND NAVY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department United States Army, from December 4, 1870, *to December* 17, 1870, *inclusive.*

COOPER, G. E., Surgeon.—By Gen'l Orders No. 28, c.s. Headquarters Department of the Columbia, announced as Medical Director of that Department.

MAGRUDER, D. L., Surgeon.—By S. O. No. 224, c.s. Headquarters Department of the Missouri, granted leave of absence for thirty days, with permission to apply for an extension of sixty days.

GHISELIN, J. T., Surgeon.—By Gen'l Orders No. 28, c.s. Headquarters Department of the Columbia, relieved from duty as Acting Medical Director of that Department.

CLEMENTS, B. A., Surgeon.—Returned to the Post of Jackson Barracks, New Orleans, Louisiana, December, 6, 1870.

TILTON, H. R., Assistant Surgeon.—By S. O. 224, c.s. Headquarters Department of the East, granted leave of absence for thirty days, with permission to apply for an extension of sixty days.

MCMILLIN, THOS., Assistant Surgeon.—By S. O. 181, c.s. Headquarters Military Division of the Pacific, granted leave of absence for sixty days, with permission to apply for an extension of four months.

KOERPER, E. A., Assistant Surgeon.—By S. O. 151, c.s. Headquarters Department of Texas, the leave of absence granted him in S. O. 129, c.s., Headquarters Fort Clark, Texas, is extended fifteen days.

O'REILLY, R. M., Assistant Surgeon.—S. O. No. 177 c.s. Headquarters Department of California, confirms telegram authorizing him to delay fourteen days in reporting at Headquarters Department of California.

O'REILLY, R. M., Assistant Surgeon.—By S. O. 171, c.s. Headquarters Military Division of the Pacific, the permission to delay fourteen days reporting at Headquarters Department of California, is extended forty days.

DICKSON, J. M., Assistant Surgeon.—By S. O. dated Headquarters Department of the Platte, November 15, 1870, granted leave of absence.

MINOR, W. C., Assistant Surgeon.—By Gen'l Orders No. 119, War Department, Adjutant General's Office, November 25, 1870, retired from active service.

Medical Items and News.

CONTAGIOUS DISEASES.—Dr. Moreau Morris, City Sanitary Inspector, submits the following comparative statement of Contagious Diseases reported to the Bureau for the fortnights ending Dec. 10th and 17th, 1870:—

Week Ending	FEVER.			Small-pox.	Scarlatina.	Measles.	Diphtheria.
	Typhus.	Typhoid	Relapsing.				
Dec. 3.	4	45	7	2	61	43	7
Dec. 10.	1	21	7	2	79	50	8

Week Ending	FEVER.			Small-pox.	Scarlatina.	Measles.	Diphtheria.
	Typhus	Typhoid	Relapsing.				
Dec. 10.	1	21	7	2	79	50	8
Dec. 17.	2	16	4	2	55	79	11

DR. CLYMER'S LECTURES ON THE PALSIES, ETC.—*The London Medical Times and Gazette*, October 15, 1870, says:—"Recent numbers of the *New York Medical Record* contain some excellent lectures on nervous diseases by Dr. MEREDITH CLYMER, who has devoted much attention to the subject. Those on Charcot's and shaking palsy are peculiarly valuable." These lectures have been translated into French by Dr. P. VERGELEY, one of the Editors of *l'Union Médicale*, published at Bordeaux, and are now appearing in that journal.

BARON VON LIEBIG.—This eminent *savant* is now in Engadine, Switzerland, for the recuperation of his health.

Original Lectures.

TUBERCULOSIS OF CHILDREN.

BEING REMARKS MADE BEFORE THE NEW YORK MEDICAL JOURNAL ASSOCIATION.

By J. LEWIS SMITH, M.D.,

NEW YORK.

SYMPTOMATOLOGY.

Symptoms.—The symptoms in tuberculosis of children arise, in part, from the dathesis, and in part from the tubercles. Before the period of tubercles, there are signs of failing health, such as loss of appetite, flabbiness of the soft parts, or emaciation, lassitude, and loss of strength. These symptoms continue after the formation of tubercles, and increase.

The features are ordinarily pallid, but during the paroxysms of fever, to which tubercular patients are subject, they may be flushed. Lividity of the features, due to imperfect decarbonization of the blood, occurs, if there are enlarged bronchial glands which compress the vessels within the thorax, or if there is extensive pulmonary tuberculization, or pulmonary tuberculization, whether extensive or not, which is complicated by capillary bronchitis or pneumonia.

The skin is nearly natural, or it loses its flexibility and softness, and becomes dry and rough. In some patients there is, at times, general or partial furfuraceous desquamation of the skin, due to exaggerated development of the epidermis. Children, like adults, notwithstanding the general dryness of the surface, are liable to perspirations at night and in sleep. This symptom is less frequent at the commencement than at an advanced period, and in acute than in chronic cases, in the very young, namely, those under three or four months, than in older children. It is more abundant about the head and limbs than elsewhere, and is sometimes confined to these parts.

Anasarca is not infrequent. It sometimes arises from obstructed circulation, in consequence of compression of the thoracic vessels by enlarged lymphatic glands; in other cases it is due to diminished plasticity of the blood, a result of the tubercular cachexia. The latter is the more common cause. It is not an important symptom, on account of the small amount of serous transudation, and the character of the parts in which it occurs.

Emaciation, already alluded to, is early, constant, and progressive. Under the age of six or eight months it is less marked than in older children, many preserving considerable rotundity of features and form even in advanced tuberculosis. The failure of the strength corresponds in amount and progress with the emaciation. Slight at first, and exhibited only by a degree of lassitude, it gradually increases, till for weeks before death the little patient is fatigued by the ordinary muscular movements, and is disposed to keep quiet.

The nervous system is not ordinarily affected except in cases of intra-cranial tubercles. In acute tuberculosis, or tuberculosis complicated by severe inflammation, there may be agitation and delirium, especially at night.

In most patients the mucous membrane of the buccal cavity presents its normal appearance, with the exception of a moist fur upon the tongue, and a paler hue than normal of its surface generally. In acute tuberculosis, and in cases complicated by inflammation, the tongue is sometimes dry and brown. The appetite may be normal till the close of life, or it is poor or changeable. Occasionally it is increased, although the disease is progressing. The bowels are regular or relaxed. Diarrhœa may be a prominent symptom, even when there are no intestinal tubercles or ulceration. Meteorism and fulness of the abdomen are common.

Fever, constant, but usually with evening exacerbations, is rarely absent. It continues for weeks or months. During the exacerbation the pulse rises to 120, 140, or even to 180 beats per minute, and there is a corresponding exaltation of the temperature, which in the latter part of the day, without inflammatory complication, ranges from 100° to 102° or 103°. The fever is a symptom of diagnostic value as regards the nature of the disease, though it does not indicate the seat of the tubercles.

In addition to the symptoms now described there are *special* symptoms, due to tuberculization of the different organs. In young children, on account of the fact already referred to, namely, the tendency to a generalization of tubercles, there is apt to be a blending of the symptoms which arise from different organs, but with care it is not difficult in most instances to isolate and refer them to their proper source. The following are the symptoms which arise from tuberculization of the more important organs. 1st, Encephalon. The symptoms produced by tubercles of the encephalon vary according to their seat and size, and the structural changes in surrounding parts to which they give rise. Meningeal tubercles, which are located for the most part in the meshes of the pia mater, and by preference along the course of the small arteries, are ordinarily small, not more than a line in diameter, and they may remain latent for a considerable time. In the majority of cases, however, they sooner or later cause meningitis, the symptoms of which are well known and need not be described. But tubercles in this situation do sometimes give rise to symptoms when there is no meningeal inflammation. They occasion congestion of the surrounding vessels, and serous transudation, and if developed on the under surface of the pia mater they may produce symptoms by encroaching upon and irritating the brain; for they are sometimes so much imbedded in the convolutions that careful examination is required in order to determine that they are meningeal, and not cerebral. Among these symptoms may be mentioned headache, frontal or occipital, sometimes intermittent, nausea, melancholy, and in certain cases the symptoms produced by the serous transudation.

The symptoms of *cerebral* are in part similar to those of meningeal tubercles, but in most cases others of a neuropathic character are present, which serve for differential diagnosis. The differences as regards the symptoms of different patients affected with cerebral tubercles are attributable in part to the fact that their size and rapidity of growth vary, but more to the difference in their seat; for any part of the brain may be the seat of tubercles, though certain portions, as the cerebellum, are more frequently affected than others.

The child with cerebral tubercles is quiet, but irritable and easily excited. Delirium is not common, but many before the close of life exhibit a degree of mental dulness. The headache, common in cases of cerebral as well as meningeal tubercles, may be nearly general, or it is frontal, parietal, or occipital, according to the seat of the tubercles. It is often lancinating, often intermittent.

Clonic convulsions occur towards the close of life. Exceptionally they are among the earliest symptoms. Observations have failed to establish any relation between the seat of the tubercles and the localization of the convulsions. The convulsions may be unilateral, while

the tubercles are in both hemispheres; or general, while the tubercles are on one side only.

The severity and duration of the convulsive attacks, and the frequency of their occurrence in tuberculosis of the brain, vary greatly in different patients. They have been attributed to softening of the cerebral substance, which sometimes occurs immediately around the tubercles, to local congestions excited by them, and also to serous effusion in the ventricles. The convulsions sooner or later end in paralysis or coma.

Contraction, or tonic convulsion of certain muscles, is sometimes observed. Its most frequent seat is the muscles of the back, and of one or both of the lower extremities. It is a late symptom. It occurs in those cases in which there is softening around the tubercles, and usually in the muscles of the opposite side.

Paralysis is also a late, but not an unfrequent symptom. It is preceded by headache, and sometimes, as already stated, by convulsions. Occurring as a symptom of tuberculosis of the brain, it is due either to pressure on a cranial nerve, or to compression, and perhaps softening of the cerebral substance. The paralysis may be paraplegic, commencing as feebleness of the lower extremities, and increasing until it becomes complete, or a more or less complete hemiplegia. In paraplegia due to tubercles of the brain, the cerebellum is, as a rule, their seat, while paralysis of one side, or of certain muscles of one side, indicates tubercles of the opposite cerebral hemisphere; but there are exceptions. Paralysis of the third cranial nerve gives rise to ptosis, of the sixth to paralysis of the external motor nerves of the eye, and therefore to internal strabismus.

Feebleness or loss of vision, inequality, oscillation, and finally dilatation of the pupils, are not unfrequent symptoms of tuberculosis of the brain, and they possess great diagnostic value. Atrophy of the optic nerve, causing amaurosis, sometimes results from tubercles as well as other tumors of the brain. Atrophy of this nerve occurs not only when the tubercles are so located as to press on the optic tract, in which case the explanation is apparent, but also in certain patients, when the tubercles are in other parts of the brain. In these last cases it is thought by Brown-Séquard and others that the imperfect nutrition of the nerve is due to contraction of its nutrient vessels, produced by the tubercles through reflex action.

In tuberculosis of the brain symptoms pertaining to the respiratory, circulatory, and digestive systems are either absent or are quite subordinate to those of a neuropathic character. Slowness of the pulse, with or without intermittence, has sometimes been observed, and it is therefore a symptom of some diagnostic value. Towards the close of life both pulse and respiration are apt to be accelerated. Vomiting, constipation, and retraction of the abdomen, which are so common in meningitis, are only occasional symptoms.

Bronchial Glands.—During the progress of tuberculosis, hyperplasia, cheesy degeneration, and softening may occur of various lymphatic glands throughout the body, but the bronchial and mesenteric are not only those which are most frequently affected, but they are the only glands, unless in exceptional instances, which materially increase the danger or give rise to special symptoms. These symptoms either have a mechanical cause, namely, the pressure exerted by the enlarged glands on contiguous parts, or they are due to softening of the glands and consecutive inflammation and ulceration.

The following are the principal symptoms due to compression. Some of them are not infrequent; others are rare. Compression of the pulmonary veins retards the flow of blood from the lungs to the left auricle, giving rise to congestion, and, in extreme cases, œdema of the lungs, with sanguineous extravasations into the lung substance, congestion of the right cavities of the heart, hepatic veins, and of the systemic capillaries generally. Compression of the pneumogastric nerve, or of the recurrent laryngeal, which is the motor nerve of the laryngeal muscles, produces a cough which is apt to be spasmodic, and modifies the voice. The cough resembles that of pertussis, and has been mistaken for it, but it is not so violent or protracted. The voice, clear and natural at first, becomes by degrees hoarse or feeble from deficient innervation of the laryngeal muscles.

An enlarged gland, or mass of glands, lying against the trachea or one of the bronchial tubes (this may occur with tubes up to the third or fourth division), and pressing its walls inward, obviously obstructs more or less the current of air. If there is considerable obstruction, a loud sonorous râle is produced, which is heard distinctly at a distance from the chest, obscuring other râles. It is loudest when the patient is agitated, and it sometimes intermits. Feeble respiratory murmur, dyspnœa, and a cough, are not infrequent in bronchial phthisis. Diminished intensity of the respiratory murmur is general or partial, according to the seat of the compression. It has been most frequently observed at the summit of the lungs. In certain patients this symptom is not constant, the respiration being for a time feeble and then normal. The dyspnœa may be a prominent and distressing symptom, the alæ nasi dilating, and the infra-mammary region sinking with each inspiration. The cough which occurs when a gland presses on the trachea or bronchial tube, is due to the tracheitis or bronchitis to which the pressure gives rise. If ulceration occur at the point of pressure, the cough continues as long as the ulcer remains. Compression of the large veins within the thorax, which return blood from the head and upper extremities, causes more or less congestion of these parts, with, perhaps, transudation of serum in the subcutaneous cellular tissue, and within the cranium. Rarely a softened gland by ulceration gives rise to other symptoms than those mentioned, namely, hemorrhage by ulceration into a vessel, or pleuritis or pneumonitis if the ulceration is towards the lungs.

Improvement in the condition of the patient affected with bronchial phthisis is not unusual. It may be permanent, but in most patients it is temporary, so that in a few weeks or months the symptoms are as severe as before. The improvement is due to softening and elimination of a gland which had given rise to symptoms by its mechanical effect, or by the inflammation which it had excited.

Physical Signs.—These are absent or obscure in the incipient disease, when the glands are small, and they are most marked in those cases in which the glands are so large as to press on the thoracic walls, since they then become the medium for the transmission of sounds to the ear. The part of the thorax against which they most frequently press is the dorsal vertebræ, from the first to the sixth, and each side of the vertebræ, and less frequently the upper third of the sternum. The physical signs are dulness on percussion over the interscapular space, and perhaps, though to less extent, over the upper part of the sternum, and bronchial respiration in the same situations. Occasionally a bruit can be detected, due to the pressure of a gland on one of the large vessels of the chest.

Lungs.—A cough is one of the earliest and most persistent of the symptoms of pulmonary tuberculosis. It is so rarely absent that those of largest experience do

not meet with more than one or two such cases. It varies in severity and frequency. If the tuberculosis is acute and its course rapid, the cough, even from its commencement, is frequent, so as to weary the patient and deprive him of needed rest. But in ordinary cases, namely, when the disease is chronic, the cough commences gradually, attracting little attention by its infrequency, but becoming more frequent and painful as the disease advances.

Ordinarily the cough is dry in the first weeks or months, but it becomes looser in the course of the disease, from the greater amount of bronchial inflammation. In exceptional instances the cough has a spasmodic character, like that produced by pressure of an enlarged bronchial gland on the pneumogastric or recurrent laryngeal nerve. This occurs from the accumulation of viscid mucus in one or more of the bronchial tubes, usually in dilated portions of them, from which it is with difficulty expectorated.

The respiration in pulmonary tuberculosis is accelerated in proportion to the degree of tuberculization. Tuberculization of a considerable part of both lungs gives rise to dyspnœa, especially when, as is ordinarily the case, bronchial, pulmonary, or pleuritic inflammation has supervened. Pneumonitis or pleuritis gives rise to the expiratory moan, and as these inflammations, when induced by tubercles, are protracted, this symptom may continue for weeks or months.

Patients under the age of six years do not expectorate, or but rarely. After this age expectoration is not common in the commencement of pulmonary tuberculosis, but in the confirmed disease it is a pretty constant attendant of the cough. Hæmoptysis is also rare under the age of six years, and less frequent subsequently than in the adult. It is most apt to occur in those cases in which there is already passive congestion of the lungs, produced by the pressure of enlarged bronchial glands in the manner already described. Patients old enough to make known the subjective symptoms, sometimes complain of fugitive pains under the sternum or between the shoulders.

Physical Signs.—In young children the physical signs of incipient pulmonary tuberculosis are wanting, or are so obscure as not to be readily recognized. This is due to the small size and dissemination of the tubercles. In older children, because, as a rule, the tubercles are aggregated, and more frequently at the apices of the lungs than elsewhere, as in the adult, the physical signs appear early, and are readily recognized. In the advanced disease, whether in infancy or childhood, when inflammation and more or less destruction of the lung substance have occurred, the physical signs, so far from being obscure, enable us in most cases, in connection with the history, to make an immediate and positive diagnosis.

In most children affected with pulmonary tuberculosis the irregular and imperfect expansion of the lungs produces by degrees changes in the shape of the thorax, which are apparent on inspection. In some the lungs being habitually imperfectly inflated, the obliquity of the ribs is increased, and the thorax consequently elongated, while its antero-posterior and transverse diameters are diminished. This obviously increases the convexity or arch of the diaphragm, so that this muscle sometimes lies against the thoracic walls as high as the ninth or even eighth rib. If the costal cartilages are yielding, there is anterior flattening of the chest and depression of the sternum; if they are firm, on account of the more advanced age, the chest remains circular.

Another shape of the thorax is not infrequent in feeble tubercular children, especially infants, who have suffered from repeated attacks of bronchitis. It occurs also in the non-tubercular, if the conditions which favor it are present. The conditions are, on the one hand, feebleness of the patient, with diminished force of respiration and impaired resiliency of the ribs; and, on the other, obstruction by mucus of one or more of the bronchial tubes. Occlusion, more or less complete, of a bronchial tube, and consequent obstruction to the current of air, produces a corresponding degree of collapse in the portion of lung to which the tube leads. The portions which collapse are, in most cases, the lower lobes, and the thin anterior margins of the upper lobes. This causes lateral depression of the lower ribs, except such as are pressed outward by the abdominal viscera, and an anterior projection of the lower part of the sternum. The shape of the thorax in these cases differs from that in rachitis, in the fact that the lateral depression does not extend to the upper ribs, nor does the upper part of the sternum project.

Certain precautions should be observed in examining the chest by percussion and auscultation. The child should sit or recline, with the arms and shoulders in the same position, and the axis of the trunk straight. Inclination of the trunk to either side, raising or depressing a shoulder, may produce an appreciable difference in the two sides as regards the physical signs. Percussion of the two sides should be practised at the same stage of respiration. A slight difference in the degree of resonance does not afford proof of disease, unless it is observed at different examinations; for in feeble children it often happens that all portions of the lungs do not expand alike, so that where we have noticed slight dulness at one visit, it may by the next have disappeared, or even at the same visit if forcible inspirations are excited.

The physical signs ascertained by palpation, auscultation, and percussion are, as in the adult, vocal fremitus, bronchial respiration, bronchophony, and dulness on percussion. In those cases in which the tubercles are mainly at the apices of the lungs, diminished expansion of the infra-clavicular region is observed during inspiration, and this part of the thoracic wall is permanently depressed so that the clavicles are unusually prominent. If there is emphysema this flattening does not occur, or is slight. Dulness on percussion, though more frequently observed in the infra-clavicular region than elsewhere, may be present in different isolated places. If pneumonia supervene, the dulness not infrequently extends over a considerable part of one lung. The crack-pot sound is often observed on percussion, but it possesses no diagnostic value. It can often be produced, when there is no pulmonary disease, by percussing over a bronchus.

Bronchial respiration and bronchophony are important signs, as indicating solidification of the lung, but they do not show whether the solidification is tubercular or pneumonic, or the two conjoined. This must be determined by the history of the case, the extent of surface over which these signs are heard, and their persistence. When the tubercles begin to soften, and the lung tissue breaks up, moist râles appear, often hoarse and gurgling, obscuring the bronchial respiration. A cavity in the lung, or pneumothorax, is attended by the same physical signs as in the adult.

Pleura.—Little need be said in reference to the symptoms and physical signs of tuberculosis of the pleura, since this affection is in most instances associated with tuberculosis of the lungs, and is not distinguishable from it. But now and then the pleural tubercles are numerous and large, giving rise to symptoms, while those of the lungs are small, few, and without symptoms, or attended by symptoms which are

quite subordinate. Either the costal or visceral portion of the pleura may be the seat of tubercles. They are developed directly under the pleura, or upon its free surface. They are very apt to occur in the newly-formed connective tissue which results from pleuritis. Those located upon the free surface, or under the costal pleura, rarely soften, while those under the visceral pleura sometimes soften and cause ulceration. Occasionally numerous aggregated tubercles form a firm continuous layer upon the surface of the pleura, preventing, if upon the visceral pleura, full expansion of the lung. This may give rise to a degree of dulness on percussion, and feebleness of the respiratory murmur. Ordinarily, however, in this form of tuberculosis the symptoms and physical signs, so far as any are observed, are due to the pleuritic inflammation which the tubercles excite.

Stomach and Intestines.—The symptoms in tuberculosis of the stomach and intestines vary according to the seat and stage of the tubercles. Their most common seat is the small intestine, and more frequently its lower portion, near the ileo-cœcal valve, than its upper or central. They are rare in the duodenum or contiguous part of the jejunum. They are developed ordinarily in the connective tissue, either that lying under the mucous or the serous surface.

Gastro-intestinal tubercles are often accompanied by ulceration of the adjacent mucous membrane. But in a certain proportion of cases there is probably no causative relation of the tubercles to the ulcers, for ulceration of this membrane is not infrequent in the tuberculosis of children, when there are no tubercles in the walls of the stomach or intestines. The following statistics of Rilliet and Barthez, relating to this point, will aid in an understanding of the symptoms:

Tubercles in walls of stomach, 7 cases. { **with ulcers, 6 cases.** / **without " 1 case.**

Ulcers of gastric mucous membrane, without gastric tubercles, 14 cases.

Tubercles in small intestines, 82 cases. { **with ulcers, 70 cases.** / **without " 12 "**

Ulcers without tubercles in small intestines, 51 cases.

Tubercles in large intestine, 15 cases. { **with ulcers, 10 cases.** / **without " 5 "**

Ulcers in large intestine, without tubercles, 47 cases.

The ulcers have vascular, thickened, and infiltrated borders. Their diameters vary from a line to half an inch or more, and their general form is circular, or, if two or more unite, irregular. Tubercular ulcers of the stomach are mostly in the great curvature, those of the small intestines in the ileum and lower part of the jejunum, and those of the large intestine in the cœcum.

Tubercles, whether gastric or intestinal, are not at first accompanied by symptoms, or the symptoms are obscure and ill-defined. Symptoms arise when inflammation occurs in the adjacent tissues. Diarrhœa is one of the most common and persistent of the symptoms. The alvine discharges are brown and thin, and sometimes in advanced cases very offensive. They may be streaked with blood which has escaped from the ulcers. Intestinal tubercles, developed immediately underneath the peritoneal coat, sometimes cause local peritonitis, usually of little extent. This gives rise to circumscribed pain, tenderness, and more or less meteorism.

Diagnosis.—It is evident from the foregoing description of symptoms that the diagnosis of incipient tuberculosis is much more difficult in children than adults. Before commencing the examination it is advisable to learn the hereditary tendencies of the family and the history of the patient, especially as regards antecedent diseases or debilitating agencies, and the duration of the symptoms.

Tuberculosis of the encephalon is diagnosticated with more difficulty than that of the thoracic or abdominal organs; but certain of these organs are in most cases tubercular at the same time, and the knowledge of the fact that they are affected aids in the diagnosis of the disease of the brain or its meninges. Among the symptoms which possess diagnostic value may be mentioned cephalalgia and more or less fever, with exacerbations in the commencement of the disease, and at a more advanced period strabismus, inequality or irregular action of the pupils, impairment of vision, retraction of the head, and convulsive movements or paralysis.

In certain cases careful observation and discrimination of symptoms are requisite, in order to determine whether they arise from intra-cranial tubercles or from congestion of the brain caused by obstruction in the venous circulation by the pressure of enlarged bronchial glands.

The diagnosis of bronchial phthisis, when the glands are still small, is necessarily uncertain, on account of the absence of symptoms. When they have increased in size and are so located as to press on the pneumogastric or recurrent laryngeal nerve, producing the spasmodic cough already described, the differential diagnosis between that disease and pertussis may be made by attention to the following facts: Bronchial phthisis occurs singly, and is non-contagious, while pertussis occurs as an epidemic, and with evidences of contagion. There are no successive stages, namely, those of catarrh, paroxysmal cough and decline, as in that disease, and the cough, though paroxysmal, is short, and without hoop or vomiting.

In feeble children, with inherited tubercular diathesis, emaciation, sweats, and a chronic cough, with the absence of pulmonary symptoms, should excite suspicions that the bronchial glands are involved. The evidence is almost conclusive if the cough becomes paroxysmal, and there is a loud, persistent, tracheal or bronchial râle.

In certain of the patients affected with this form of the disease, we have seen that the prominent symptoms are due to compression of one or more of the large vessels in the chest. Compression of these vessels, and consequent retarded circulation, may be confidently referred to enlarged bronchial glands, since aneurisms, carcinomatous or other tumors, which would produce a similar result, are very rare before puberty. Sometimes the diagnosis is rendered certain by the physical signs observed by auscultation, and percussion over the sternum and the interscapular space. The condition of the external glands should also be observed, as those of the axilla, neck, and groin.

The diagnosis of pulmonary, though more readily made than that of intra-cranial and bronchial tuberculosis, is often difficult and uncertain. This is, in part, explained by the fact that the tubercles are so frequently disseminated, while emaciation and a chronic cough are not infrequent from other causes than tubercles. Rachitis, intestinal worms, dentition, simple tracheal or bronchial inflammation, may be attended both by a chronic cough and emaciation. Caution is therefore requisite in order to avoid a grave error in diagnosis. Precipitancy in the diagnosis of doubtful cases is worse than indecision, and it is often best to postpone an expression of opinion as to the nature of the disease till the case has been observed for a few days.

The significance and importance of the symptoms, physical signs, and other facts on which a diagnosis

must be based, have already been sufficiently pointed out. It is difficult, in fact in certain cases impossible, to discriminate between simple cheesy pneumonia and cheesy pneumonia which has ended in the formation of tubercles. The patient has an attack of catarrhal pneumonia; but instead of absorption of the inflammatory product, cheesy infiltration occurs, and the lung in places becomes infiltrated with pus, softens, and breaks down. The patient presents the symptoms and physical signs of phthisis. He may recover after a protracted sickness, or may die. The disease may, and often does, remain a pneumonia; but this is a condition of the lungs which favors the development of tubercles, and in a certain proportion of cases tubercles do form in the last weeks of life. Though the differential diagnosis in such cases between simple pneumonia and tuberculosis supervening on pneumonia is impossible, practically the discrimination is unimportant, as the same treatment is required.

Advanced pulmonary tuberculosis, except when it supervenes upon pneumonia, can in most instances be readily diagnosticated by a careful examination. Still it is to be recollected, as already pointed out, that certain of the symptoms and physical signs, which occurring in the adult would afford almost positive proof of pulmonary tuberculosis, in children not infrequently have a different origin.

The diagnosis of tubercles in the abdominal organs is facilitated by the presence of symptoms which indicate at the same time tuberculosis of the lungs. Among the chief diagnostic signs of tuberculosis of the peritoneum may be mentioned meteorism and a degree of tenderness on pressure. But there is danger of mistaking the tympanitic state of the intestines common in ill-nourished infants and the rachitic, or the fulness due to enlarged spleen or liver, to that occasioned by peritoneal tuberculization, and vice versâ. The history of the case, and a careful examination of accompanying symptoms, and the shape and feel of the abdomen, usually suffice to establish the diagnosis. In simple gaseous distension of the abdomen there is an absence of the symptoms, general and local, which attend tuberculosis; rachitis occurs at an earlier age than peritoneal tuberculosis, and digital examination, aided by percussion, enables us to diagnosticate enlargement of the liver or spleen.

Tubercular enlargement of the mesenteric glands cannot be positively diagnosticated when they are small. When they have attained such a size that they can be felt through the abdominal walls, palpation in connection with the history and symptoms of tuberculosis suffices to establish the diagnosis. The glandular tumor can be diagnosticated from other tumors by the fact that they are tender on pressure, and occupy the umbilical region, while fecal tumors are not tender and are located in the iliac or lumbar region. Gastro-intestinal tuberculosis cannot be positively diagnosticated. Protracted diarrhœa, or frequent attacks of diarrhœa, not readily controlled by medicine, and occurring in tubercular cases, are probably associated with intestinal ulceration; but in only a certain proportion of cases of ulceration are there also tubercles in the walls of the intestines.

Prognosis.—Death is the ordinary result of tuberculosis in the child, as it is in the adult; but now and then one recovers. Hospital statistics show that the average duration of the disease is from three to seven months. Under favorable circumstances it is more protracted, even to two or three years. Those succumb soonest who inherit a strongly-marked tubercular diathesis, live in damp, dark, and ill-ventilated apartments, and whose diet is scanty or of poor quality. Therefore in the poor quarters of the city tuberculosis presents a worse form and pursues a more rapid course than among families in better circumstances.

Favorable prognostic signs are absence of tubercular diathesis, good appetite and general health, with little emaciation, infrequency of cough, with respiration, pulse, and temperature nearly normal. Such symptoms may afford hope of recovery with judicious regimenal and therapeutic measures. On the other hand, if the symptoms are grave, death is inevitable, unless in bronchial phthisis, in which, even when there is considerable urgency of symptoms, the offending gland is sometimes eliminated by softening and ulceration, and the patient improves temporarily, if he does not ultimately recover. Complete and permanent recovery is, however, quite exceptional.

Death in tuberculosis of children may occur from exhaustion induced by the general disease, or from the local effect of the tubercles. Thus in intracranial tuberculosis it may result from coma, in pulmonary tuberculosis from dyspnœa—though more frequently from exhaustion—in that of the bronchial glands from coma, dyspnœa, exhaustion, or even from hemorrhage, in that of the abdominal organs from peritonitis or protracted diarrhœa.

Treatment, Prophylactic.—Though tuberculosis is so obstinate and fatal, it is often in our power, if forewarned, to avert it. A nursing infant, whose mother has the disease, should be immediately taken from the breast and intrusted to a wet-nurse. The health of the mother as well as infant requires this. If the father has the disease, and the mother's milk is inadequate or of poor quality, and the infant is under the age of six months, the same change should be made, rather than supply the deficiency by artificial feeding. Children who are weaned should have plain but nutritious and easily digested diet, a part of which should be milk. If the predisposition to tuberculosis is strong, a little alcoholic stimulant may be allowed three or four times daily in the milk, though with the risk of creating an appetite for it. To an infant two or three drops of Bourbon whiskey may be given for each month of its age, and to children of three to five years a teaspoonful. Residence in an airy and salubrious locality, out-door exercise, a scrupulous avoidance of exposure by which a cold might be contracted, are necessary in order to the continued latency of the diathesis. Loss of flesh or appetite, or other evidences of failing health, indicate the need of additional measures of a therapeutic character. Iron, with cod-liver oil, citrate of iron and quinine, elixir of calisaya bark, or other tonic, should be employed in connection with the alcoholic stimulant and suitable regimen. By the employment of such precautionary measures as soon as indicated, multitudes of children might be saved from this disease who now perish.

Curative.—The treatment of the general disease should be the same in children as in adults. The medicinal curative agents which are required in ordinary cases are cod-liver oil, iron, or other tonic, and an alcoholic stimulant given three or four times daily. The oil is less unpleasant and more readily taken when combined with the stimulant. An eligible mixture is equal parts of cod-liver oil and wine of iron, or cod-liver oil with half its quantity of Bourbon whiskey, and a few drops of the tincture of chloride of iron. It should be given after nursing or the meals. At the age of one year two drops of the tincture of iron and a teaspoonful of cod-liver oil would constitute an ordinary dose.

If the cod-liver oil is not tolerated, or if it impairs

the appetite, it should be discontinued. In cases of diarrhœa it is of little or no benefit, and it may do harm. Under such circumstances patients sometimes do better with simple regimenal measures, aided by alcoholic stimulants, and one of the least unpleasant of the tonics, as wine of iron or the calisaya bark. The regimen already recommended for prevention is also required as a part of the curative treatment.

Certain modifications of treatment are demanded on account of the localization of the tubercles. Intracranial tuberculosis, as soon as diagnosticated, should be treated by pretty decided doses of iodide of potassium, though, unfortunately, there is little prospect of improvement. The glandular disease, whether bronchial or mesenteric, requires the iodide of iron, with or without that of potassium. Pneumonitis or pleuritis, so frequent a complication of pulmonary tuberculosis, requires emollient poultices, with moderate counter-irritation, and the judicious use of opiates with stimulants. The peritonitis occurring in abdominal tuberculosis, which is usually circumscribed, is best treated by fomentations and poultices, with opiates, and the diarrhœa by subnitrate of bismuth and chalk, five to ten grains of each, or the bismuth with Dover's powder; or a more active astringent.

Original Communications.

BLOODLETTING IN OBSTETRIC PRACTICE.

BEING THE ABSTRACT OF A PAPER READ BEFORE THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK, DEC. 5, 1870.*

By FORDYCE BARKER, M.D.

Recently, while attending a patient in confinement, he found indications for venesection; and, not having a lancet at hand, stepped into the nearest instrument-maker's to procure one. There was not a lancet to be found in the shop! The attendant apologized; said they had little call for that article, but they had some making, which would be ready in a few days. This was an amusing index of the change which had come over the practice of the profession in the last twenty or thirty years. Doubtless, our predecessors bled more times in a week than we in a year. In all his obstetrical practice, in consultation, for the last fifteen years, he could not recall a single instance where bloodletting had been even alluded to, except in a few cases of puerperal convulsions.

He had made a careful examination of the standard authorities in midwifery of thirty years ago, a long list of whom he cited. By one or all of them bloodletting was recommended for the following, among other conditions, in gestation, parturition, and the puerperal state:

In gestation: for uterine irritation, uterine plethora, erratic pains, cramps of the lower extremities, spasmodic cough, palpitation, pruritus, solitude, anxiety, drowsiness, anasarca, to prevent abortion, and to promote expulsion where abortion is inevitable. One woman was reported as having been bled eighty-six times in one pregnancy, and another eighty-seven times!

In parturition: for false pains, where the patient is plethoric; for irregular uterine contractions with pains feeble; for extreme rigidity of the os, or of the perinæum; to prevent inflammation; to prevent, and to cure, convulsions.

In the puerperal state phlebotomy constituted the most essential part of the treatment for the arrest and cure of all the post-partum inflammations, metritis, peritonitis, etc.; and by many it was recommended in phlegmasia dolens.

As some one of the above conditions was pretty sure to occur in the course of pregnancy, parturition, or the puerperal state, it came about that almost every patient was bled at least once, and often many times, with every child. No doubt we could, nearly all of us, recall the picture of some jolly old grandmother, proud of her eight or ten children, and of the blood she had shed for each of them.

But were our predecessors all wrong, and is the recent practice all right? For his own part, the speaker found that, as he gained wider experience, he was gradually coming to bleed more frequently. This change in his practice had not arisen from any belief in a change in the constitution of the patients. But he had, for a considerable time, had a growing impression that this resource had been too much neglected—an impression recently strengthened by the suggestions contained in the introductory address of Dr. Benjamin W. Richardson. That paper, which he was surprised to see commanding so little attention in his country, no man in active practice could read without being instructed.

The speaker proposed to consider bloodletting exclusively as a remedy in obstetric practice. It was in this that it was formerly resorted to most frequently, and carried to the farthest extreme; and it was this in which it was now perhaps most neglected. He would speak of it in the diseases of pregnancy, in the complications of labor, and in the affections of the puerperal state.

Vertigo, flushing of the face, etc., used to be regarded as evidences of cerebral congestion, and bloodletting as the main remedy. To Cazeaux belonged chiefly the merit of calling attention to the fact that the most frequent of those disorders formerly attributed to plethora were really due to impoverishment of the blood, although doubtless many had before noticed that hydræmia gives much the same symptoms as plethora. Andral, indeed, had pointed out that a too great and a too small number of corpuscles passing through the vessels of the brain produce effects very similar. Cazeaux's tonic treatment had become generally adopted; but one result of this might be that real plethora was sometimes overlooked. Some feeble women would have the constitution so changed in pregnancy as to gain strength and flesh, and might become truly plethoric; and this might interfere with the fœtal circulation and produce derangements in the maternal. That the cessation of the fœtal movements is sometimes due to this cause was shown by the return of those movements when the mother is subjected to a moderate loss of blood.

Even in hydræmia there might be a serous congestion, a too great quantity of blood, where benefit would be derived from venesection followed by a tonic regimen and good diet.

Uterine and renal congestions—the former seen much oftener in feeble women—almost always made their appearance at the menstrual periods, when the woman would complain of tension and swelling of the abdomen, and of weight in the pelvis. If proper measures were not employed to reduce the congestion of the uterus, there might be a little flow of blood from it and some danger of abortion. This was commonly accompanied by marked vesical irritation. If

* Vide page 520.

these symptoms did not readily disappear, the speaker believed bleeding to be the best treatment, following it by chlorate of potassa and iron.

Of renal congestion he would only say that it is but recently we have learned that in some cases of cerebral congestion the primary hyperæmia is to be found in the kidneys. This was seen especially in the albuminuria of pregnancy. For a few years past he had succeeded in warding off the convulsions due to this cause by slight venesections, with a certainty such as he had never before gained by other means. He related a recent case of sudden and severe convulsions, in which he had taken thirty ounces of blood, besides inducing active purgation by elaterium. The woman had a few more convulsions, but completely recovered in a few days. On the same day with this case, he had seen, in consultation, a primipara in uræmic coma a few hours after delivery. Two or three days before, she had begun to complain of a fixed pain at the fundus uteri, which was unaccompanied by contractions, and which did not yield. The labor was rather tedious; the forceps were employed, and a dead child was delivered. The placenta came away readily, and on its uterine surface was found an organized clot as large as a man's hand. The patient died in three hours after he saw her. But little urine could he drawn from the bladder, and that was highly albuminous. It would seem as if nature had tried to relieve the renal congestion, and to relieve it by bleeding.

It was a great mistake to suppose that bloodletting should never be resorted to except in the sthenic condition. Some of the most decided benefits he had seen derived from it had been in cases of patients extremely anæmic. As an instance, he was called to a chlorotic woman in the last days of gestation; found the heart's action labored and tumultuous, the face covered with perspiration, and every symptom of the greatest distress. As speedily as possible he was opening a vein, when the gruff, hearty voice of old Dr. Francis greeted him with, "Well done, good and faithful servant." The abstraction of sixteen ounces of blood relieved the pulmonary œdema and the distension of the right heart, and doubtless saved the woman's life. Two days later the woman was delivered of a dead hydrocephalic child, after discharging an immense quantity of waters. "She must have discharged a tub-full, sir," said Dr. Francis.

In parturition there was now little occasion for the use of bleeding to overcome causes of delay. In the warm douche, belladonna, and chloroform, we had better means of softening the os. Its chief use now, at this period, was to prevent threatened convulsions or apoplexy, by relieving spinal or cerebral congestion. This it would do where the tendency to convulsions was owing to over-stimulation of the nervous system from excess of blood, or to pressure from the same cause. Again, where the danger was dependent on uræmia, this measure was of cardinal importance. The speaker fully concurred with Dr. Richardson, that in cases of uræmic poisoning, where the urine is almost suppressed, where the convulsions are strong, and the coma is deep, there is no remedy so sure as the lancet. To bleed is to remove tension from the brain, to remove congestion from the lung and make free the breathing, to remove congestion from the kidney and restore its functional activity. Moreover, it should be considered that we are at the same time removing with the blood the poisonous material with which it is charged. Of two animals, each with the function of one kidney suppressed, one will live if, when uræmic convulsions appear, blood be drawn; the other, let alone, will die.

In inflammatory affections the indications were to prevent or arrest the progress of the inflammation, or to remove its results. Although it was probably even now generally believed that bloodletting would fulfil one or more of these indications, yet we had other means safer and quite as sure; and the speaker had not for many years employed it in any post-partum inflammation. Perhaps he had sometimes erred in this. One case in particular he looked back upon with regret that he had not drawn blood. A beautiful young lady, four days after her first confinement, was attacked with very violent metroperitonitis, and, in spite of the best professional counsel, died on the twelfth day. She had lost very little blood at the time of delivery.

It was even to be feared that, in the effort to prevent post-partum hæmorrhage, we may have carried too far our measures for producing immediate contraction of the uterus. The speaker had been much impressed by a remark of Dr. Peaslee's, in reference to an amputation at the shoulder-joint, that as much blood ought to be lost in the operation as had before circulated in the limb, in order not to induce a real plethora. He had added that this principle was of equal importance in midwifery, and a perfectly healthy woman should lose at least a pound or two in labor. Dr. Barker could not agree fully with this proposition, but thought it applied justly to some exceptional cases.

On bloodletting in puerperal fever the Doctor had before expressed his views; and they had not been essentially modified by his last fifteen years' experience, including a lying-in service at Bellevue Hospital.

In certain rare cases of puerperal mania, venesection might be of service. Although in the great majority of instances this affection resulted from defective nutrition and nervous exhaustion, yet this was not true of all. A young lady, who had been doing so well after confinement that the Doctor had ceased his visits, began on the thirteenth day to exhibit symptoms of mania, which soon became uncontrollably violent. She had complained of pain in her breasts; her pulse was somewhat quickened; temperature 103° F. With great difficulty she was held while a vein could be opened; but as the blood flowed she became quiet, sank down in the bed, and fell into a sound sleep while he was bandaging the arm. It was estimated that about fifty ounces were drawn. The cure was complete, and after this convalescence was rapid, without an untoward symptom. The Doctor had never seen a case of puerperal mania so promptly and happily yield to treatment.

A NEW OPERATION FOR THE RADICAL CURE OF INGROWING TOE-NAIL.

By F. B. LAWSON, M.D.,

NEW YORK.

The operations for ingrowing nail are so numerous that it seems like an imposition to add another to the list; but as on the one hand they are all either palliative or quite formidable in character, and as on the other these objections cannot be made to the operation that is about to be described, there is an excuse for making the addition. Neither is it necessary, at this time, to call attention to the causes of inversion of the nail, or to refer to the several operations that have been suggested for its relief; these details can be obtained in another way.

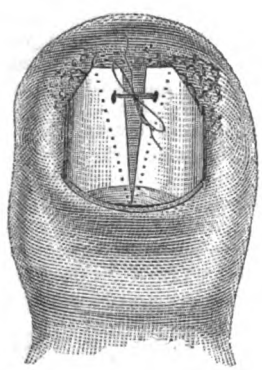
Taking the disease as it presents itself to the surgeon, the question arises relative to preparatory treatment. In the majority of cases none is required. There are

some, however, in which fungous granulations must be removed, or inflammation reduced by antiphlogistic methods, especially by the application of poultices. This having been done, the patient is ready for the operation, and my method of performing it is to remove a V-shaped piece of the back of the nail, and draw the edges together with a ligature, and at the same time, or subsequently, to remove the inverted portion with the scissors.

The dimensions of the V-shaped piece will vary in each case. Its apex should extend at least to the lunula, and in the majority of cases to the edge of the scarfskin which overlaps the nail at its root. Its base should be about a quarter of an inch in breadth, but if both corners of the nail are inverted, it will be necessary to make it broader. This piece should always be removed with the point of a scalpel, and not with the scissors, and the incision made on an angle, so that it can be easily separated from the matrix.

A silk ligature, well waxed, is preferable to every other (I have used wire and found that it did not answer the purpose as well), and can be used in two ways, either by notching the free edge of the nail, or by passing a needle through it. I prefer the latter method, for then there is no chance of its slipping. If the nail is thick, it will be necessary to bore through it with the point of the knife; then the needle, which should be small and curved, is easily managed. In this instance I always use the surgeon's knot, and draw it as tightly as the condition of the nail will admit of, and fix it with a bow knot.

It may be advisable at the time of the operation to remove the inverted portion or portions. This is, however, not always necessary, nor is it always possible without giving the patient great pain; but whenever it is done the scissors will be found to be the proper instrument, and with it the corner or corners of the nail should be cut out obliquely, as shown in the cut, which also illustrates the other steps of the simple operation described.



As a dressing, when one is required, I have had most success with Goulard's cerate. A small bit of carded cotton may be soaked with it, and the whole packed into the sides and under the edges of the nail. It should be changed daily, and the parts well washed with warm water and soap. On seeing the patient two or three days after the operation it may be well to tighten the ligature; hence the advantage of having used the bow knot. Treatment may be discontinued after all inflammation has subsided, but the ligature should be allowed to remain for a number of weeks—until the nail has grown considerably—when it may be removed by the patient, who should be instructed to do it by cutting the nail square across and even with the end of the toe.

I have performed this operation for nearly three years on a large number of cases—many of them were Dispensary patients—and in every case with complete success.

The advantages of this method over every other with which I am acquainted, are almost too numerous to mention. Instead of disabling the patient, it gives almost immediate relief. The tightening of the ligature removes the source of irritation, as well as narrows the end of the nail, thereby preventing subsequent trouble. If there are granulations under the nail, as is not unfrequently the case, the pressure produced by the ligature destroys them, and also acts as a compress to the inflamed tissue. The operation is, for the most part, painless and bloodless, so that chloroform or ether is never required. Within two or three days even the patients have so far recovered as to be able to wear a shoe, and walk without difficulty, and will often present themselves at the end of this time, with little or no inflammation of the parts, and express their gratitude for having been so easily and quickly relieved.

31 West Thirty-first Street.

Progress of Medical Science.

THE BIPOLAR METHOD OF TURNING.—At a recent meeting of the Boston Obstetrical Society, Dr. Fifield alluded to the method of turning by *one or two fingers*, which had long been advocated by Dr. Robert Lee. Barnes, he thinks, does not give him sufficient credit for this. Dr. Fifield has twice used the bipolar method of turning, with perfect success.—*Boston Med. and Surg. Journal.*

WOMB DISEASE AND APHORISMS OF UTERINE THERAPEUTICS.—Dr. E. N. Chapman, late Professor of Obstetrics in the Long Island College Hospital (*Med. and Surg. Reporter*), gives a summary of 354 cases of womb-disease, and the following aphorisms of uterine therapeutics: Uterine disease invariably falls within the limits of the menstrual age, neither arising before the advent, nor continuing after the decline of this epoch. In no case did the attack precede puberty, or follow the climacteric period; the youngest subject under treatment being 18, and the oldest 56 years of age. A change of life—a retrograde step by which the internal genitalia return to their original condition—is Nature's mode of cure—a mode invariably certain. Chronic cases of congestion are not benefited by a menorrhagia or a metrorrhagia, the discharge being a mere leakage from overcharged vessels that have lost their contractility. The duration of uterine disease may be coextensive with that of the menses, unless pregnancy or art interferes. The longest time recorded is 28 years, the shortest, 3 days; the mean, 3 years and 3¼ months. The prognosis, even with the unfavorable surroundings of a dispensary practice, is extremely flattering. Of the 219 cases treated locally, 165 were cured and 15 benefited. One recovered by a change of climate, and one by the growth of an ovarian tumor.

It may be safely premised that, in private practice, 85 to 90 per cent. of uterine cases admit of a perfect restoration to health.

Vaginitis is part and parcel of uterine congestion, and is due to a repletion of the erectile coat of the vagina. This repletion distending the vascular papillæ, induces mucous inflammation, which, being consecutive, abates proportionately with the underlying congestion

that feeds the papillæ, but is not benefited by a specific treatment. Of the 165 cases cured, 40 had this complication.

PROGRESSIVE MUSCULAR SCLEROSIS.—Drs. William Ingalls and S. G. Webber, of Boston, Mass. (*Boston Med. and Surg. Journ.*), report a fatal case of *Progressive Muscular Sclerosis*. It occurred in a child, of Irish parentage, 5 years and 2 months old. At the age of 3 years he was quite a healthy child, but about that period he began to move and act as though he had less strength than usual; this condition increased, and the spinal column became very weak, and the "inward crook" of it was noticed by the mother. On the day of admission into the Children's Hospital, Boston, the spine presented a regular and exaggerated curve inward, from the third and fourth dorsal vertebræ to the sacrum. This shape comes well under the name given by Duchenne—"saddle-back." The patient died on the 5th day after admission, having had convulsions on the day of his death.

The attending physicians remark that the first case of this disease was noticed only about 12 years ago, and they have been able to find the records of only 41 cases; 21 in German, 13 in French, and 7 in English medical journals. Dr. Meredith Clymer's able paper on the "palsies," published July 15th, 1870, in the MEDICAL RECORD, is alluded to; but Drs. I. and W. have neglected to notice the first recorded case of *progressive myro-sclerosic palsy*, by Dr. Edward Meryon, who on the 9th of December, 1851, read a paper before the Royal Medical and Chirurgical Society, and described the history of this case.

CURE OF ULCERS BY TRANSPLANTATION OF SKIN.—In the *Medical Times and Gazette* of Oct. 29th is an article by Mr. Dobson of the General Hospital, Bristol, Eng., on the treatment of ulcers by transplantation of skin, according to the method of M. Riverdin, in which he describes the mode of procedure and reports several cures. He says: "To sum up the behavior of these minute particles of skin in their novel situation, once for all, I may say, speaking generally, that at or about the second day the cuticle begins to separate; that by the fourth day only a faint pale spot marks the insertion, or there may be no evidence of it left at all; by the sixth day a faint vascular tuft of granulation appears; this becomes glazed, and in a few days more the usual covering of cicatrix is formed. The patch is usually circular and presents slight ridges: its aspect, as a whole, is difficult to define in words; it bears some resemblance to a flattened, badly-marked limpet shell; it requires to be seen to be understood. This patch continues to increase in size circularly, until it reaches its maximum of growth." "I have never seen a patch larger than a florin" about 1¼ inches in diameter (sic), and I have now seen large numbers of them; I should say that their average growth will not exceed the size of a sixpence. This, then, is their true history as I have observed it. Of course it is subject to variations, and here and there a graft may fail either from a fault in the skin or granulations, or from some want of delicacy or from carelessness in the manipulations, for it is just one of those procedures which, though simple and easy of execution, require care and attention to minute details.

In the Reports of Hospital Practice, in the same journal, the editor gives the results of this mode of treatment as pursued in the St. George's, Westminster, University College, Middlesex, and Charing Cross Hospitals, the Seamen's Hospital at Greenwich, and the Devon and Exeter Hospital, in all of which it had been successful in aiding the cicatrization of large granulating surfaces.

A NOVEL FRACTURE.—A case of fracture of the anterior superior spinous process of the ilium by muscular contraction, is reported by Drs. S. Joy and J. W. McWhinnie, of Montreal (*Canada Medical Journal*), occurring in a medical student, aged seventeen, who was engaged in a foot race where a certain distance had to be run, then to turn and run back. In the exertion of turning he felt something snap in his right hip, walked a few steps and fell. In two weeks the patient made a good recovery without displacement.

Although the patient was a very muscular young man, yet it is difficult to believe that the sartorius muscle is sufficiently powerful to fracture its point of origin, but the case was examined most carefully by these surgeons, and they believe there was no room for doubt about the diagnosis.

THE USE OF CHLORAL IN CEREBRO-SPINAL MENINGITIS.—Dr. James S. Whitmire, of Metamora, Ill. (*Chicago Med. Examiner*), considers this drug, in the treatment of this disease, a great acquisition to our stock of heroic remedies. In two cases where chloride was given his success was complete.

CLOSURE OF THE EUSTACHIAN TUBE.—In proof of its extreme infrequency, Lindenbaum has yet been able to collect, in the *Archiv für Ohrenheilkunde*, only four authentic cases of closure of the pharyngeal orifice of the tube, and these were usually produced by cicatrization from syphilitic ulcers.

THE PHENOPHTHALMOTROPE.—Dr. Donders, of Utrecht (*Med. and Surg. Reporter*), has invented a machine for elucidating the movements of the eye-ball, which he calls the *phenophthalmotrope*. By means of it the mathematical analysis made by Prof. Helmholtz of the ocular movements may be practically demonstrated.

OINTMENT OF MERCURIC NITRATE.—R. Rother (*The Pharmacist*) recommends the subjoined formula in the preparation of mercuric nitrate: Take of mercury 1½ troy ounces; nitric acid, sp. gr. 1.42, 3½ troy ounces; lard (pure), 16½ troy ounces. Dissolve the mercury in 900 grains of the nitric acid, with the aid of heat, and keep the solution gently warm to prevent crystallization before it is used. Melt the lard with a moderate heat, then add the remainder of the nitric acid. When effervescence ceases and the liquid only boils even under an increased heat, remove the mixture from the fire, and when it begins to stiffen, add the mercurial solution, and mix thoroughly.

HYDRATE OF CHLORAL IN DELIRIUM TREMENS.—Wm. S. Bowen, M. D., U. S. N. (*Boston Med. and Surg. Journ.*), advocates the use of this remedy in mania-a-potû, and publishes a case being confirmatory of its efficacy. He administered it in doses of from 20 to 60 grains, in water flavored with ol. menth. pip.

CANTHARIDINATE OF POTASSA.—In a recent number of the *Journal de Chimie Médicale* M. Delpeche calls attention to the defects of the ordinary preparations of cantharides; the proportion of the active agent, or cantharidin, varying, the presence of fatty or oily substances sometimes causing the absorption of a dangerous poison, and the rosin or turpentine employed in the composition of the plaster being an unnecessary irritant. In place of this he recommends the *cantharidinate of potash*, which is of very stable composition—has no odor, and possesses a vesicant action in a high degree. He recommends, as the best formula for the plaster, gelatine, 2.09 parts; water, 10 parts; alcohol, 10 parts; cantharidinate of potash, 0.20 parts; glycerine, 9.05 parts. The mass should be equally spread on thin gutta-percha, a definite quantity being present in each square inch.

New Instrument for Securing Pedicle.—Dr. Graily Hewitt, Professor of Midwifery in the University College, writes in the *British Medical Journal* for October of "a new instrument for securing the pedicle in the operation of ovariotomy." He describes it as follows:—

A framework of steel shaped something like a shoe buckle, measuring two inches and a half by one inch and three-fourths; the piece of steel of which the instrument is made being two-eighths of an inch wide, and one-eighth of an inch thick, is provided with studs or buttons, eight in number, three on two sides, and one on each of the other two sides. These buttons project three-eighths of an inch from the steel framework. It is to be used in the following manner: The pedicle, having been roughly trimmed, is perforated with a needle armed with a double strong thread, or whipcord ligature, in two or three places, according to the width of the pedicle. It is then tied in segments, and the opposite ends are secured to the buttons of the framework above, one by one. The pedicle is now surrounded by the framework, while the cut edge of the pedicle is freely open to inspection and treatment in the centre; the tightness with which the ligatures are applied keeping the pedicle from slipping into the abdomen.

The advantages of this method are, he thinks, that the wound can easily be dressed; the pedicle is always accessible. The framework makes no pressure whatever on the edges of the wound at the point where the pedicle emerges, and the healing and covering of the whole wound are facilitated.

New African Ordeal Poison.—MM. Rabuteau and Peyre have been experimenting with the root of a plant in use at the Gaboon as an ordeal poison and locally known as m'boundon or icaja. It will be remembered that it was from this source that the highly valuable Calibar bean was obtained and utilized in medicine.

The authors state that, even in very dilute decoctions, it is very bitter and appears to contain one or more alkaloids, since the aqueous solution is largely precipitated by iodide of potassium, and also by phosphomolybdic acid. The poisonous effects of this substance bear some similarity to the effects of brucia, but the authors state that, under certain conditions, this poison does not hurt man. Some of the lower animals are readily killed by it. A dose of three milligrammes of the alcoholic extract, placed under the skin of a frog, kills it, and rabbits and dogs are killed by doses of from fifteen to twenty-five centigrammes of the same extract introduced into the stomach.

Chlor-alum, the new Antiseptic.—Under the name of chlor-alum, Mr. John Gamgee (*British Med. Journal* for Oct. 10th) has introduced to the medical profession and to the public generally a solution of hydrated chloride of aluminium, which bids fair to take an important position among the antiseptics and disinfectants. Its chemical activity depends, to some extent, upon the amount of potential muriatic acid. Many bad smells which carbolic acid might indeed overcome in virtue of its own strong odor, but which it cannot destroy, are at once removable by chloride of aluminium. Thus the fœtid stench from cabbage-water is at once removed by chlor-alum, but not by carbolic acid. In this respect chlor-alum has some advantages over even permanganate solution, which, as is well known, destroys fœtor by oxidizing the fœtid substance, but which is almost powerless against, or acts very slowly upon, some varieties of malodorous things that have the property of not being very easily oxidizable.

The smell arising from putrid fish affords a specially favorable case for exhibiting the powers of chlor-alum. The agent in general use to which chlor-alum most closely approximates is chloride of zinc, which, like it, is specially potent against offensive organic ammonias. It appears that even in strong solutions it is not corrosive and will not injure textile fabrics. Its price is about one-tenth of that of the chloride of zinc.

Prevention of Scarlatina.—In a pamphlet lately published in England on *Scarlet Fever and its Prevention* by Dr. William Budd, and reviewed in the October number of the *Brit. Med. Journ.*, the author declares that so remarkable has been his success with the method of isolation and disinfection which he has practised, that for a period of twenty years he has never known this disease to spread in a single instance *beyond* the sick room, and in a very few instances within it.

Sea Sickness. — Dr. O. Rapin, of Switzerland, says that he has found that the nausea and vomiting produced by swinging and sea-sickness can be arrested by applying to the epigastrium a layer of wadding dipped in collodion. It should extend from the xiphoid cartilage to the umbilicus, and be left until it falls off. If the adhesion should be imperfect, the application should be renewed. Several persons, he says, have tried this plan with benefit.

The explanation which he gives of it is, that the action of the peripheral nerves is interrupted just in the same way as the pain of calculi in the bile-passages or ureters is sometimes mitigated by the application of castor oil and collodion.—*Br. Med. Journ.*, Oct. 15th, 1870.

Mollities Ossium and Fracture of Ribs in Insane.—In the *Edinburgh Med. Journ.* for Nov. there appears an article by W. Lauder Linsay, M.D., Physician to the Murray Royal Institution for the Insane, at Perth, in which he speaks:

1st, of *mollities ossium* in the insane, to show that it sometimes exists in as marked a degree as among the sane; and as bearing on,

2d, *Rib-fracture* in the insane, to point out (*a*), the frequency of self-injury; (*b*), the very slight violence sometimes required for rib-fracture; (*c*), the existence of serious or fatal surgical injury without external marks or any relative symptoms; (*d*), the importance of post-mortem examination in the detection of masked or unsuspected injury; (*e*), the desirability of distinguishing from each other injuries that are 1st, accidental, 2d, self-inflicted, 3d, the result of mal-treatment by attendants; (*f*), the injustice of attributing rib-fractures and similar injuries necessarily to attendants; (*g*), the frequency of such injuries is a necessary consequence of the non-use of mechanical restraint; (*h*), those who are responsible for such injuries are, therefore, those who have advocated the *non-restraint dogma;* (*i*), there are *no* pathological lesions in this affection peculiar to insanity.

Senile Contraction of Vagina.—In a recent number of the *Dublin Quarterly Journal*, Dr. Alfred McClintock, of Dublin, calls attention to what he terms *senile contraction of the vagina.* He says: "In what I may call the minor forms of this contraction, we find simply a transverse fold of the vagina projecting inwards, and presenting to the finger a sharp concentric edge. This seldom engages more than one-third or one-half the circumference of the canal, and is generally situated on the posterior wall, a little better than half way up; but I have also met with it higher, or implicating the os itself by one or the other of the semilunar valve-like projections. There is another and more important variety of this species of contraction which I have occasionally observed. *The capaciousness of the vaginal cul-de-sac, so noticeable in women who have borne children, gives place*

to the "contraction I now wish to describe, in which there takes place a progressive diminution of the calibre of the vagina, not throughout its entire extent, but commencing at its summit and progressing downwards."

He speaks of two cases in which the constriction had become so great that the os and cervix were quite hid from sight, the stricture being barely large enough to admit a probe.

All the cases he has met with were in women between the ages of 50 and 60, one only being under 50. In his diagnosis he eliminates the usual causes mentioned by Dr. Thomas as productive of atresia vaginæ, viz.: arrest of development; prolonged and difficult labor; chemical agents locally applied; mechanical agencies; sloughing, the result of impaired vitality; and syphilitic or other extensive ulcerations and regards it as some sort of atrophy connected with the decline of life and extinction of functional activity in the generative organs, and dependent upon lesions produced during delivery.

THE ACTION OF DIURETICS.—Dr. F. B. Nunnelly (*Med.-Chir. Transactions*) details his experiments with diuretics, and arrives at the following conclusions: Citrate and acetate of potash only slightly increase the quantity of water excreted by the kidneys, while they materially lessen the amount of urea and of solids excreted. Spiritus ætheris nitrosi slightly increases the amount of urinary water, and decidedly reduces the quantity of urea and solids. Oil of juniper slightly reduces the amount of water excreted, and appreciably increases the urea and solids.

A MECHANICAL ANÆSTHETIC.—The *Practitioner* for December contains an interesting article by the late Dr. A. Waller on the compression of the vagus nerve as a means of producing anæsthesia. It is claimed that by vagal pressure the patient can be speedily and safely brought into a state of complete insensibility, and that several surgical operations have been performed with entire absence of pain. It appears to produce a condition specially favorable to the reduction of dislocated bones. Attention was directed to this subject by Dr. Waller, shortly before his death, in the hope that it might be found of practical value in a large number of cases where ether or chloroform is now required. This may be only the revival of an old fashion, as the Assyrians are reported to have produced anæsthesia by compression of the cervical vessels during the performance of circumcision.

THE USE OF LOBELIA IN TETANUS.—Dr. George O. Butler, of Cleveland, Ohio (*Med. and Surg. Reporter*), reports three cases of tetanus successfully treated by lobelia inflata. From the use of this remedy in these cases the following conclusions may be drawn:—1st. Lobelia, as a powerful nauseant, will control the circulation. 2d. As a prostrating nauseant, it proves antispasmodic. 3d. Lobelia, as a powerful sudorific, eliminates whatever materies morbi is conceived to act as the exciting irritant in tetanus.

IPECACUANHA IN TYPHOID FEVER.—John Stephen, M.D., of Reading, Pa. (*Med. and Surg. Reporter*), employed this drug in two very severe cases of typhoid fever, with speedy recovery. His conclusions are as follows:—These two cases of fever, as far as two cases can go, show in a surprising manner the power which ipecacuanha in large doses possesses, when guarded by opiates, of not only checking the further increase of the fever poison, but also of completely neutralizing the effects of that which has already morbidly tainted the "fluid flesh" and deranged life's electric chords; bringing back through the medium of the blood and nervous system life's unbalanced forces to a healthy equilibrium; restoring to the brain its normal functions; checking the rapidity, while it gives tenacity to the heart's action; recalling the skin to its accustomed uses, and changing as if by magic the enteric complication; by restoring to the bowels, whether the morbid condition be one of diarrhœa or of constipation, their normal physiological action.

THE DISCRIMINATION BETWEEN SYPHILIS AND SCROFULA.—F. F. Maury, M.D., Surgeon to the Philadelphia Hospital (*Med. and Surg. Reporter*), in a lecture on "Infantile Syphilis," states that the parallelism between congenital syphilis and scrofula, when closely traced, so approximates that no human being can discriminate between them. He also believes that the unfolding of the next twenty-five years will establish the identity between so-called scrofula and inherited or quaternary syphilis, and this pathway leads him to the broad field of legalized prostitution, of which he is an advocate.

SIMPLE METHOD OF MEASURING THE SPECIFIC GRAVITY OF SMALL QUANTITIES OF URINE.—A writer in the *Boston Medical and Surgical Journal* has so often known the important fact of the specific gravity to be left out of a report on a specimen of urine for the want of enough to fill the urinometer, that the following simple rule is given:—Add to the quantity of urine to be examined as many equal volumes of water as may be necessary to float the scale of the urinometer. Multiply the excess of the specific gravity of the mixture above 1,000 by the whole number of volumes employed, add it to 1,000, and the result will be the specific gravity of the urine.

GELSEMINUM SEMPERVIRENS.—Dr. E. P. Hurd, Newburyport, Mass. (*Boston Medical and Surgical Journal*), has been in the habit for some time of using a tincture of the root of the yellow jessamine, and believes that as a cardiac sedative we have not its equal in the whole range of the materia medica. It relieves in a marked manner the shortness of breath and palpitations of all forms of heart-disease. He has seen more prompt and decided benefit from its use in chronic valvular disease than from digitalis. The dose may be three drops of the saturated tincture every two, three, or four hours. The gelseminum is combined with Hoffman's anodyne and tincture of lavender, and is believed to have a specific effect on the vaso-motor nerves, stimulating them, and thus equalizing the circulation and lessening the labor of the heart. It also allays the nervous irritability, is surer than veratrum or prussic acid, and safer than digitalis.

MUCUNA PRURIENS.—A pharmacist in Savannah, Ga. (*Boston Med. and Surg. Journal*), has ascertained that the terrible itching caused by the injudicious handling of mucuna pruriens (cowhage) can be at once relieved by the application of camphor liniment.

OBSTINATE HICCOUGH.—According to Dr. Juaritz (*Siglo Médico*), a physician being seized with a serious hiccough, while convalescing from gastric fever, drank in mistake an infusion of mustard, and obtained relief.

TORTICOLLIS.—In the advanced stages of this affection, Dr. J. Russell Reynolds, in his "System of Medicine," states that no mode nor combination of modes of treatment has availed to cure, or even to modify it. He has used all kinds of soothing applications, has employed electricity in every form, and failed to influence the disease when once it has become firmly fixed. When the malady has existed for a few months only,

he has found that the continuous current is useful, and at that period he has seen notable advantage from the continued application of morphia by the method of hypodermic injection. It is not essential that the morphia should be injected into the neck; it may be introduced into the arm or thigh, or any other convenient locality; but it is important that its use be steadily continued, and that the quantity injected be gradually increased until a definite effect is produced upon the spasm. Beginning with the tenth part of a grain, the quantity may be increased, if necessary, until two, or even three, grains are injected thrice daily; and when the patient can bear this amount the spasm has sometimes yielded.

Division of the nerves has been useless, and division of the sterno-mastoid worse than useless, for it has led to an exaggeration of the spasm in the deeper-seated muscles at the back of the neck, as Dr. R. had occasion to observe in a well-marked case that came under his notice some years ago.

HYDRATE OF CHLORAL.—Prof. Samuel G. Armor, M.D., of Long Island College Hospital (*Mich. Univ. Med. Journal*), arrives at the following conclusions as to the physiological and therapeutic action of this new drug. It cannot always be relied on as a substitute for many of the older and well-tried anodynes and nervines.

In a certain proportion of cases it produces unpleasant symptoms, such as gastric distress, difficult breathing, partial paralysis of the organs of deglutition, and a restless condition of the brain and nervous system. This is, however, largely exceptional to its general action.

These unpleasant symptoms are in many cases obviated by combining an opiate, in small sustaining doses, to the nervous system, with chloral—say the 1-12th of a grain of morphine, or 10 or 12 minims of McMunn's elixir of opium (he prefers to administer the opium separately). The action of the opium thus administered appears to be antagonistic to the sometimes depressing effects of the chloral.

Chloral should never be administered on a full stomach, neither on an empty one; intermediate periods are better. A good rule is to select a period when the stomach is empty, and have the patient take a small crust of bread or a cracker ten or twelve minutes before taking the chloral. Its action is somewhat transient. In two or two and a half hours the dose must be repeated if the first produces no effect, or if we desire to protract the action of the drug.

The protracted use of the drug is not advisable. It weakens the general vital forces, and tends to the production of anæmia.

A GOOD ANÆSTHETIC MIXTURE.—Dr. Henry F. Lyster, of Detroit (*Mich. Univ. Med. Journal*), advocates this anæsthetic mixture in private practice:

℞ Alcoholi..... ℥ ss;
Chloroformi..... ℥ j;
Æther. sulphurici..... ℥ ij.
Misce.

Before administering the above in surgical operations, he is in the habit of giving the patient a teaspoonful or two of brandy, thus corroborating the views of Dr. Warren Stone, of New Orleans, and others.

THE FORMATION OF UREA.—M. Grehaut (*Jour. de l'Anat. et de Phys.*) says that the ligation of the ureters and nephrotomy are identical in their results; they both suppress the eliminating functions of the kidneys, but present no obstacle to the formation of urea, which takes place remote from the sphere of their action.

IODIDE OF POTASSIUM AS A GALACTAGOGUE.—J. L. Van Zandt, M.D., Fort Worth, Texas (*Rich. and Louis. Med. Journal*), has accidentally found out that iodide of potassium increases the secretion of milk in nursing women, and has prescribed it in several instances since. This fact is corroborated by his friends, Drs. W. P. Burts, of Fort Worth; Patton, of Quitman; and D. P. Lipscomb, of Grape Vine Prairie, Texas. The result of treatment in these cases does not accord with the remarks of Scanzoni, who places pot. iodid. among the ischogalactics, and cites several authorities confirmatory. What the explanation of this discrepancy in results may be, he will not now attempt to say; but will only note the fact that most, if not all, of these cases had been sufferers from malarial disease, and that pot. iodid. has been found to be one of the best alteratives in chronic malarial poisoning.

RHINOPLASTY.—Dr. John E. Owens, Chicago, Ill. (*The Chicago Med. Journal*), in his "Day amongst the Surgeons of Philadelphia," says that Prof. Pancoast's rule in this operation is to make the new nose one-third thicker and longer than the normal size. He applies, at the proper time, a gutta-percha mould, with which, and a stuffing of cotton upon the inside of the new nose, he succeeds in giving this lump of flesh a shape. This mode of including the periosteum in the flap for the nose originated with Langenbeck.

Prof. Agnew, of Philadelphia, who has experimented considerably with periosteum, says that the new bone is deposited in nodules, and that even these do not always occur.

YOUNG MOTHERS.—At a meeting of the Obstetrical Society of Boston (*Boston Med. Surg Journal*), Dr. Curtis spoke of a girl at the Massachusetts General Hospital, who, two years ago, when only 13 years old, bore a child. She menstruated at twelve.

Dr. Abbot mentioned the case that occurred at the Monson Almshouse a few years ago,—the mother was 11 years old, and the father 16.

SCARLET FEVER.—During the twenty-one years from 1848 to 1868 inclusive, there were registered in England and Wales 415,982 deaths from scarlet fever and its allied disease diphtheria. It is estimated that at least 40,000 deaths have occurred in England last year.

HOUSTON, TEXAS, AS A RESIDENCE FOR CONSUMPTIVES.—Dr. James Cowling, of Houston, Texas (*New Orleans Med. Journal*), recommends this town as an excellent residence for those suffering from pulmonary complaints, from these facts: 1st. The temperature of the place is very mild; for the winter months of December, January, and February, the temperature is about 46° Fah. This includes the 24 hours round, giving to many days sufficient heat to be without fire. 2d. The breezes prevail from the south, coming from the Gulf, then blowing across the prairie, tempering them and making them very agreeable, pleasant, and healthy. 3d. Every facility exists for out-door exercise, either about down or in the sheltered woods around, or open prairie, and by railway and steamboat. 4th. There are well suppled markets, good hotels, and very agreeable society, with its advantages, although not so prominent as some already mentioned, nevertheless possessing in conjunction a beneficial influence on the patient.

Dr. Cowling, in conclusion, affirms that patients following out the above suggestions, aided by proper medical advice, may rely, in most cases, upon a great if not permanent relief.

THE MEDICAL RECORD.

A Semi-Monthly Journal of Medicine and Surgery.

A CASE OF ALLEGED MALPRACTICE.

ANOTHER case of alleged malpractice (Haire *vs.* Reese) was tried and determined in one of the Philadelphia courts at the October session. The circumstances of this case, interesting and important to the profession in several points, are as follows: Dr. John J. Reese, Professor of Medical Jurisprudence in the University of Pennsylvania, was in February, 1869, summoned to the Colored House of Refuge to see a man who had fallen from a window upon the pavement, a distance of twenty-five feet. He was bleeding from a lacerated wound of the scalp, but chiefly complained of pain in the right hip. He was removed to his home, and at his request Dr. Reese took charge of the case. After etherization a thorough examination of the damaged limb was made, and no fracture or dislocation was discovered. The injury seemed a violent contusion about the right hip, and he was treated accordingly. Three weeks afterwards, at the request of the attending surgeon, Professor D. Hayes Agnew, of the University of Pennsylvania, saw the patient in consultation, and again a thorough examination by all the known methods was made. Dr. Agnew was of opinion that the original diagnosis was correct, and that there was no evidence either of luxation or fracture. Dr. Reese continued his visits during a period of fourteen weeks, and when he ceased attendance the patient was able to walk about on crutches easily, but could not put his right foot to the ground without having pain in the hip-joint of that side. For these services no compensation was given. In the month of August following, Dr. Reese received a note from a lawyer informing him that his grateful patient had commenced a suit against him for damages on account of having, by bad treatment of his case, caused a shortening of his limb. This legal gentleman, on learning the particulars of the case, became satisfied that there were no grounds of action, and abandoned the suit. A week afterwards a second attorney gave the doctor a similar notice of suit being brought; he subsequently became satisfied that his client had no cause of action, and retired. Six months passed, when a third lawyer was found who was willing to push the case to trial, and so notified the defendant. In the meantime, Dr. Agnew, who had seen the plaintiff but once, and that in consultation, was also sued for malpractice. Dr. Agnew's case was first called up, but was postponed at the plaintiff's request, and that against Dr. Reese was tried on the 17th and 18th of October last. The ground taken by the defence was, that though at that time, a period of more than eighteen months, there was undoubted shortening of the injured limb, it was neither the result of a dislocation nor fracture which had not been recognized by the attending surgeon during treatment, but was due to an *interstitial absorption of the neck of the thigh-bone*, consequent to the severe contusion of the hip—the man had first struck the railings in his fall, before coming to the ground—that it was not present during the period of Dr. Reese's attendance, and did not show itself until several months after the injury. This plea was supported unreservedly by the testimony of Drs. S. D. Gross, Agnew, Brinton, Lewis, and Packard, all eminent surgeons of large experience; and they moreover testified that the treatment was skilful and proper. None of the surgical witnesses called by the plaintiff would say that *the shortening was the result of a previous fracture of the neck of the thigh bone.* One of the witnesses for the plaintiff, a Moses Stevenson, who had graduated in 1870, after studying medicine two years, said in the course of his cross-examination, among other bright things, that "the head of the femur may be crepitated by absorption." The judge well remarked, in his charge, of this witness's testimony, that "in his opinion it was not worth considering, and was in the highest degree discreditable to him." The other professional witnesses for the prosecution—Dr. John Hirst, a graduate of the College of Surgeons of Edinburgh, Dr. Joseph D. Scoles, and Dr. Duffee—would not say there had been a fracture, and the latter indeed was distinctly of opinion that it was a case of absorption of the thigh-bone. We may remark that Mr. James Paget published a lecture in the *British Medical Journal*, Feb. 19, 1870, on shortening of the leg as the result of direct injury to the hip, and in the *Edinburgh Medical Journal*, vol. xlvi., 1836, Mr. Gulliver has mentioned several instances of like results from contusion of the hip-joint.

The charge of Judge Thayer was an admirable one It reviewed the whole ground of action, and clearly interpreted to the jury the scientific questions at issue, and the technical testimony. He pointed out the rules of law applicable to the case in question, and plainly laid down the principle that an action for malpractice can only be sustained by positive proof of want of ordinary skill and attention on the part of the medical attendant, and that the burthen of proving it lies upon the person who alleges it. He said:

"The implied contract of a surgeon or a physician who attends a patient is, not that he will entirely effect a cure, but that he will use all known and reasonable means to accomplish that object, and that he will attend his patient carefully and diligently. His relation to his patient implies that he possesses, and will employ in the treatment of the case, such reasonable skill and diligence as are ordinarily exercised in his profession by thoroughly educated surgeons or physicians . . . and reasonable skill and diligence, means such skill and diligence as educated and faithful surgeons or physicians ordinarily employ.

"No presumption of the absence of proper skill and attention arises from the mere fact that the patient does not recover, or that a complete cure is not effected. God forbid that the law should apply any rule so rigorous and unjust as that to the relations and responsibilities arising out of this noble and humane profession. . . . On the part of the patient, it is his duty to conform to the necessary prescriptions and treatment, if they be such as a surgeon or physician of ordinary skill and care would adopt or sanction; and if he will not, or, under the pressure of pain, cannot, the surgeon or physician is not responsible for injury resulting therefrom."

These are reiterations of well-settled points of law, but they are well and honestly put.

The jury, without leaving the box, returned a verdict for the defendant, and assessed the costs upon the plaintiff.

It was but lately that we called our readers' attention to a case of alleged malpractice happening in this city, in which Dr. Lewis A. Sayre was the defendant, and which ended, too, in the discomfiture of the plaintiff, the real wrong-doer. Had these cases gone against the intended victims--for the law's uncertainty is only exceeded by the capriciousness and eccentricities of juries—neither the personal nor professional reputation of Dr. Reese or Dr. Sayre would have suffered, for both were too well-known in their respective communities to have been damaged by trumped-up charges affecting their character or their skill. Many a physician, satisfied in his conscience that he had done the best within his abilities for his patient, would, under like circumstances, have shrunk from what might be looked upon as an unequal contest, and been unwilling to face the annoyances and publicity which a trial necessarily entails, and bought off the plaintiff. Dr. Reese expressly says he might have avoided the trial "by listening to the base proposals of the plaintiff's counsel to pay black-mail." (The *Medical Times*, Dec. 1, 1870, p. 74.) We believe that Dr. Sayre could at any time have settled his case for an insignificant sum of money. Fortunately for the profession the gentlemen in these instances knew their duty to their brethren, and were willing at personal sacrifice and risk to do it regardless of consequences. Dr. Reese states that he "regarded it as a matter of principle, as a duty he owed to the profession, to meet this law-suit." The results of the Philadelphia and New York trials will no doubt do much towards putting an end to what Judge Thayer has happily called, "experiments, by unjustifiable law-suits, against skilful, attentive, and humane physicians." If this happens, the medical men of this country ought to bear in mind to whom they are chiefly indebted for such a result, and should recognize in some fit way the obligation they lie under to Drs. Reese and Sayre for their unselfish and courageous vindication of the honor of our profession.

The Medical Society of the State of New York will hold its next annual session in Albany, on the first Tuesday in February. It is to be expected that the attendance will be as full as usual, and that those who may be present may be repaid in the discussion of interesting subjects. There will be, as a matter of course, some long papers, lengthy remarks, and tedious speakers; but the listeners have learned to be courteous and considerate, and it seems to be sufficient if these authors occasionally ask the Society to *bear* with them. What can any company of polite gentlemen do when a person chooses to inflict upon them an uninteresting subject, and ingeniously insinuates every little while that he is ready to cease when he becomes a bore? Does not the very necessity for making such a remark at all, prove that the one who makes it has no conscience? If the sessions were long enough it might be very edifying to take up the history of any subject from the time of Hippocrates, or to rehash the well-known opinions of our standard authors; but the truth is, the members cannot be expected to come together to hear one individual, however learned he may be. The best test of a good paper is the discussion which it calls forth. If the original points are well and tersely taken, and the subject is at all interesting, the paper can always be made a good one; and *per contra*, a good subject can be irretrievably damaged by spinning it out to an unnecessary length. Let us hope that the majority of the papers to be presented may be short, practical, and well written.

There will be little if any unfinished business to start upon. The subject of State Registration is one of vital importance, and should be pushed. Since the last meeting much has been done in the way of starting the thing on a proper basis; it now remains for such as are interested in its success to secure a proper working of its details.

Another matter which we think it will be for the interest of the Society to discuss, is the propriety of repealing the By-law denying authors the right to publish their papers in medical journals before they have appeared in the Transactions. The volume of the Transactions does not generally make its appearance till eleven or twelve months after the meeting, and the author is compelled to wait that time before he can be heard. If his article contains any original ideas they must slumber a year before they can be presented to his professional brethren, and the chances are that what might have been new at the time the paper was read, becomes very old by the time the paper is printed. Again, all this time is lost to the profession for proving by experiment the truth or untruth of the assertions

therein contained. The number of copies of the Transactions to be published each year depends upon the Legislature, and may be large or small; and in any event but a small proportion finds its way into the hands of the profession proper, the larger number being used for campaigning purposes. Published at the expense of the State, and gratuitously distributed, its circulation as a volume cannot be damaged by containing reprints. If it were issued at the expense of the Society it would be a different matter, and its sale might be much damaged by publishing second-hand material. But the Society, while really having nothing to say as to the number of copies to be printed, and the time of their appearance, on the one hand, and not being compelled to pass the By-law on the other hand, is voluntarily doing itself great damage, in constraining ambitious authors to seek other and readier channels for their productions. We predict that the enforcement of this By-law will hereafter rob the archives of many a valuable paper. The By-law is on its face as unreasonable as it is unaccountable,—and it is the bounden duty of the Society to repeal it at once.

We are glad to see that the medical men from this city are showing more and more interest in the workings of the Society, and that each year the number in attendance increases. We hope that this will be particularly the case the coming session. New York is to furnish the President for the ensuing year—and there should be interest enough among the profession here in the choice to secure more than the usual quota of registered names.

Reviews and Notices of Books.

PATHOLOGY AND TREATMENT OF VENEREAL DISEASES, including the Results of Recent Investigations upon the Subject. By FREEMAN J. BUMSTEAD, M.D., Professor of Venereal Diseases at the College of Physicians and Surgeons, New York; Surgeon to Charity Hospital, etc. Third edition, revised and enlarged, with illustrations. Philadelphia: Henry C. Lea. 1870.

PROFESSOR BUMSTEAD'S masterly treatise on venereal is so widely known, both in this country and abroad, that it is only necessary, in calling attention to the third edition, to refer to the improvements that have been effected by revision. We have purposely delayed our notice of the present volume, in order that by comparison with former editions we might speak with confidence of the revision and enlargement. Those who already possess a standard work like that of Professor Bumstead, very naturally hesitate about the purchase of a later edition, unless assured that the improvements are such as will justify them in discarding an old book for a new one. In this instance we are convinced that the author has devoted no small amount of conscientious labor to the task of revision. He has submitted the whole work to a careful scrutiny, and many parts of it have been entirely re-written, such, for instance, as the chapters on the treatment of stricture and those relating to chancroid and syphilis. Recent investigations have given prominence to the subject of viscera syphilis, which accordingly receives all the attention that it demands. Syphilitic ophthalmia, which formed a conspicuous feature of the former editions, has also been written up to the latest period of ophthalmic knowledge; and in this department the author has been assisted by Dr. E. H. Loring. Some portions of the earlier editions, relating to questions now no longer subjects of doubt or controversy, have been omitted, and other portions have been considerably cut down and modified to admit matter of greater importance. The consequence is, that the sixty-four pages by which the volume is increased form no measure of the actual additions. The object has been throughout to supply a practical treatise on venereal diseases, adapted alike to the wants of the student and the practitioner. It was the intention to enrich the work by a series of plates and colored illustrations, but the author believes that want now fully supplied by the re-publication of Cullerier's Atlas.

We have not space to mention in detail all the improvements we observe on a perusal of the work; but we have no hesitation in pronouncing the present volume to be the best practical treatise on venereal diseases in the English language.

AN INTRODUCTION TO THE OSTEOLOGY OF THE MAMMALIA —Being the Substance of a Course of Lectures delivered at the Royal College of Surgeons of England, in 1870. By WILLIAM HENRY FLOWER, F.R.C.S., Hunterian Professor of Anatomy and Physiology, &c. With numerous illustrations. London: Macmillan & Co. 1870.

THE profession is already somhat acquainted with the able and instructive course of lectures which forms the basis of this volume; but the author has so enlarged and remodelled them as to render his work a convenient hand-book for the student of osteology. Few subjects are more difficult than that of osteology to render particularly attractive; but when men of unusual ability and attainments devote themselves to the task, even dry bones are made to a some new and interesting features. The study of osteology is naturally the foundation of all knowledge of anatomy, human and comparative; and the student of the animal kingdom cannot be too grateful for such aid to systematic investigation as that afforded by Prof Flower's lectures. Taking the human skeleton as a point of departure, the author passes easily and clearly to the consideration of those of the lower mammalia in their various modifications.

Of the twenty chapters which compose the volume before us, we find one devoted to the classification of the mammalia. The author admits at the outset that in the present imperfect condition of our knowledge a perfect classification is impossible, and he therefore regards the one adopted as merely provisional. It agrees in the main with that of Prof. Huxley, and includes three principal groups, viz.: Monodelphia, composing the great bulk of the class; Didelphia, and Ornithodelphia. One chapter is given to the general consideration of the skeleton, and four to that of the vertebra. Five chapters are devoted to the skull and the peculiar details of its construction in the various animals. The remaining chapters take up elaborately the sternum and ribs, the pelvic and shoulder-girdles, and the bones of the extremities, with their anatomical configuration and correspondence.

Having steadily in view a purely anatomical description of the bones, the author avoids all physiological considerations, though there must have been a strong temptation at times to enlarge upon the uses and adaptations of the structures so minutely described and so thoughtfully compared. The result of the plan

adhered to, however, has been to furnish within very moderate dimensions a most comprehensive work on osteology, and one which occupies a place by itself. It contains one hundred and twenty-six illustrations, nearly all original, which render material assistance in following the descriptions. Taken altogether, we regard the volume as a valuable addition to our literature, and a model throughout of conciseness and perspicuity. We advise all medical students, and those interested in any department of anatomy, to render themselves familiar with Professor Flower's method of studying osteology.

Reports of Societies.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

STATED MEETING, DECEMBER 5, 1870.

DR. ABRAM JACOBI, PRESIDENT, in the Chair.

THE PRESIDENT announced the admission to membership of Drs. Henry R. Derby, Jesse L. Morrill, J. Fitzgerald O'Connor, Samuel Sexton, and Alfred L. Carroll.

The report of the Committee on Intelligence was read by Dr. Castle. We present extracts from it under the head of *Progress of Medical Science.*

DR. BARKER read a paper on Bloodletting in Obstetric Practice (vid. page 510).

DR. PEASLEE was called upon by the President, and remarked:

In advance I will say that I do not agree with Dr. Peaslee, as quoted in the paper, any more than does Dr. Barker. But if the remainder of the paragraph had been quoted, to the effect that he had himself seen patients bled where he thought that it had prevented inflammation or other ill consequences, but that this practice should be confined to plethoric patients, and never resorted to in the anæmic, then I should be ready to endorse it fully. The opinion was expressed seventeen years ago, and I have seen no occasion to change it since. With regard to that point, I inquire of the patient, if she be evidently pretty full of blood, whether in previous deliveries she has had any great hæmorrhage, or any accident afterwards. If she has had little hæmorrhage in delivery, and has suffered from any subsequent inflammation, I allow her to bleed at least a pint, and if a quart, no matter. But with an anæmic patient, I should endeavor to preserve all the blood she has in the body, uterus and all, if I could; and should give a dose of ergot ten or fifteen minutes before the expected delivery, to act immediately after it, and save all the blood possible. I frequently hear physicians say it is their invariable rule to give ergot in that way; but I should not give it thus invariably—not to a plethoric patient, but should let her bleed as much as necessary, and then, if requisite, stop the bleeding by ergot, the hand in the uterus, etc. The pregnant uterus, weighing from two and a half to four pounds, should contain in its vessels probably more than a pint of blood. If the woman is plethoric and has in every part of the body, probably, more than the normal amount of blood, I can see no reason for retaining this extra quantity. It has been said, that the character of a person has sometimes been entirely changed in consequence of the amputation of an extremity—that a man before indifferent and sluggish would afterwards become quite energetic; the three-fourths of a man would be more efficient than the whole man had been before. This is doubtless owing to the fact that it has been regarded as a great merit in surgical operations to lose little or no blood. The limb is drained before cutting, and the surgeon prides himself on his dry amputation, in which not a tablespoonful, or a teaspoonful, of blood has escaped. I consider this the reverse of a merit in the case of a plethoric patient. If such a patient loses an upper extremity, for instance, that is entitled to something more than one pound of blood; and he should lose that amount with the limb, to leave the circulation in its normal condition. I think that the same principle applies in obstetrics, and that it is a matter of judgment in each particular case whether you shall let the woman lose a pint or more of blood, or as little as possible. I had lately occasion to deliver a woman extremely anæmic, in whose case I feared the loss of even four ounces. She lost no more than that, I think, and to that I attribute the favorable result.

With regard to venesection in eclampsia, I think there should not be a single doubt as to its immense value. I have seen, in the twenty-nine years I have been in practice, all his change of opinion on the subject of bloodletting; have seen the pendulum swing from one extreme to the other. But we are all of us taking blood in our daily practice, and cannot get along without it. If we apply a single leech we take blood; if a dozen, we take more; in venesection we take it more rapidly and with more certainty as to its amount—there is no other essential difference. Where there is extreme congestion of the vessels of the head and face, lividity of the lips, dyspnœa, sparks before the eyes, noises in the ears—where we find these signs, and the patient is getting worse, and there is nothing to contraindicate bloodletting, I should feel that I could not conscientiously withhold it. I am glad that this subject has been brought up by Dr. Barker, for it is of the greatest importance that we come to sound ideas upon it. It is said a man's opinions on bleeding are apt to be determined by the amount of blood he carries himself—if of full habit, he will use his lancet boldly; if spare and pale, he may never unsheathe it. By this criterion, I ought, perhaps, to be totally opposed to bloodletting; but I must stand as the exception to the rule, and advocate its judicious employment.

DR. ISAAC E. TAYLOR was the more pleased to hear the views expressed in the paper, because he had supposed that Dr. Barker had adopted *in toto* the ideas of Cazeaux, that the condition in pregnancy is one of anæmia. Cazeaux himself had swung completely from one side to the other, telling us that he had at first come to accept the view of the chlorotic or hydræmic condition in pregnancy wholly from the analyses of the blood conducted by MM. Andral and Gavarret, though later, in practising upon this theory, he had found clinical confirmation of it. The important practical question would seem to be how to determine, in a case of puerperal convulsions, for example, between the condition of active congestion and that of hydræmia. Are the symptoms of compression of the brain due to plethora or to serous effusion? It is not always easy to decide; and we hesitate whether to resort to chloroform, tartar emetic, and venesection, or to quite an opposite course. Though by no means an advocate of frequent bleeding, yet the speaker thought that, if these two conditions could only be clearly distinguished, there would be no treatment of greater value in the cases indicating it. He wished that Dr. Barker had given the diagnostic marks more fully.

DR. BARKER, being called upon to reply, said: If I understand the question rightly, it has reference to the methods of diagnosis between active sanguineous

plethora and the serous plethora which occurs in anæmia. I agree with Dr. Taylor, that this is one of the most difficult points in practical medicine, and often can be settled only by the nicest discrimination. Yet with reference to the practical therapeutic measure of bloodletting I have considered the decision comparatively easy. The view I have advocated in the paper is, that in a certain class of cases of anæmia, or hydræmia, the deficiency of red corpuscles may be accompanied with excess in the quantity of blood, such as to produce local congestion--whether of the kidney, most important of all; of the uterus, jeopardizing the continuance of pregnancy, if not the life of the mother; or of the brain, which often occurs as a result of puerperal convulsions. In these exceptional cases of local congestions occurring in the anæmic, bloodletting may be necessary, though during gestation the amount of blood taken must be small, and limited strictly to the relief of the local congestion, the general condition of the patient being met at the same time by the most nutritious meat diet, and by ferruginous tonics. Bleeding in the convulsions of parturition comes under a different category. There we bleed only to prevent lesion of the brain in consequence of the convulsion—to prevent apoplexy. The apoplexy, when it occurs, is not the cause of the convulsion, but its consequence, by a mechanism which a glance at the conditions involved will readily explain. The laryngeal spasm and the tonic contraction of all the muscles of respiration stop the aëration of the blood, and interfere with its passage through the lungs, producing a great accumulation in the right cavities of the heart. The contraction of the abdominal muscles forces the blood out of the great vessels of the abdomen, and aggravates this condition; while the return current from the brain is still further interfered with by the pressure of the sterno-mastoids and the platysma upon the veins of the neck. It is not strange that, under these conditions, either the delicate vessels of the brain should give way, or serous transudation through their walls take place; and to prevent this it may become imperative to diminish the volume of blood, even in an anæmic patient. In convulsions after labor where much blood has been lost—in a case of placenta prævia, for example—no sensible man would think of venesection. Here the convulsion is due to the hæmorrhage, to loss of muscular and nervous power, and our grand effort must be to restore the exhausted nerve-force. Opium is the great remedy here, and even alcoholic stimulants may be required.

Dr. F. D. Lente had been much gratified at hearing the paper, and thought it time the question of bloodletting should be reopened. It would be strange, indeed, if the eminent men of the last generation, whom Dr. Barker had named, and a host of others almost as eminent, had no ground whatever for their reliance upon a measure which they regarded as their great remedy. These men were, perhaps, even closer observers than are we at this day; for the multiplication of the instruments for physical diagnosis would seem rather to have blunted our observing faculties. In an obstetric practice of twenty years, the speaker had seen many cases benefited by bloodletting. There were some instances where this measure seemed to force itself upon the physician, though he might be unable to assign the definite reasons for it. He was speaking especially of cases of threatened uræmic convulsions, which probably constituted nine-tenths of those in which the question arises.

But he had seen many more patients benefited by other remedies than by bleeding; and to discuss the question properly, we should consider the effect of bloodletting, not by itself, but in comparison with that of the other powerful measures now at our command. Doubtless the disuse of venesection could be ascribed in no small degree to the introduction of other means having a similar immediate effect, without the remote ill consequences of the spoliative treatment. Veratrum viride, though scarcely to be employed in pregnancy, was little inferior to bloodletting in the certainty with which it reduces pulse and temperature. Specially applicable to the pregnant and parturient conditions were the inhalation of chloroform and the hypodermic injection of morphia. The speaker had seen patients saved by these means in cases where, in former times, bloodletting would have been the only remedy, and the physician would have been accounted a murderer if he had failed to employ it. He had seen cases where convulsions went on for a week, kept in check only by the administration, during the whole period, of morphia hypodermically, and of chloroform. He had never regretted the use of these agents in any instance, and, on the whole, he should rely upon them in preference to bloodletting. It was objected that opium was dangerous in uræmia, and, especially in children, where there was inflammation of the brain or its meninges. In cases of infantile convulsions, where everything else had been tried in vain, he had given it freely, and, he was confident, had saved the lives of the children.

Dr. James L. Brown.—I shall venture to speak merely because I think I represent a class of physicians whose experience has fallen within the period, of the last fifteen years or so, in which bloodletting has hardly been practised at all. During that time I have never seen venesection done, and I think I am not alone in this experience. Now it is a very interesting point to me to know whether this change in practice is due merely to a fluctuation in fashion, or is based upon sound reason. The question is asked, Can it be that all those eminent men, who used to bleed so freely, were mistaken? I think Dr. Barker has himself answered this question in giving the long list of ailments in which those old authorities all agreed to bleed—ailments of the most diverse and even opposite character, in many of which we now know beyond a doubt that bleeding is injurious. You could not now find a man to endorse that list.

There were three conditions particularly mentioned by Dr. Barker as furnishing indications for bloodletting—congestion of the uterus, congestion of the kidney, and congestion of the brain. I have seen a good many cases of midwifery, but I have never seen one where I could diagnosticate congestion of the uterus during pregnancy. As to congestion of the kidneys, it is so closely allied to cerebral congestion in the production of convulsions, that I think the two can hardly be separated. What we young men want is to know precisely the indications which call for venesection. It has been said that they are very difficult to define. I think they must be. There is want of precision in the very terms used to express these indications. Puerperal convulsions, for example, constitute no definite index of the patient's condition. In one woman they may be due to chronic Bright's disease, which has been simply aggravated by pregnancy. In such a case no man would think of bloodletting, for no amount of it could relieve the uræmia, as it could not remove the renal lesion. It is a question whether or not venesection is of service in the capillary congestion of the kidney, to which it is generally believed that convulsions may often be attributed. And as to cerebral congestion, it is well known that there are those who deny that bleeding can affect it. "No amount of bloodletting,"

says Bennett, "can diminish the amount of fluids in the cranium," which practically amounts to the same thing.

If we leave the older men and try to settle this question by the clinical practice of the writers of our own day, we find little in the way of definite directions for the employment of venesection. Trousseau very positively forbids it in all such cases as have been referred to here; he thinks it can only hasten the patient's demise. So, too, with many other writers. It becomes pretty difficult, therefore, for us, who are not familiar with this treatment, to find any clear rules for its application. We certainly cannot be expected to employ it in the absence of such definite indications, for the removal of blood must always be regarded, I think, as a serious evil, only to be tolerated when necessary for the removal of a still greater one. As to the so-called condition of plethora, I doubt if there is such a thing. I have never yet seen a man whom I thought to have too much blood in his veins. Dr. Chambers, in his *Renewal of Life*, says that he not only does not himself believe in the existence of the plethoric condition, but he does not know any intelligent physician who does believe it. If it be true that nature sometimes makes more blood than is good for a person, I should like to know how to recognize the fact.

I have not assumed that I could throw any light on this subject, but I have ventured to ask these questions, because I think there are many who, like myself, prefer specific details to generalizations. I do not think that the profession has dropped bloodletting without good reason. It is noteworthy that it has not simply modified its practice in this respect, as it has modified its heroic dosing since homœopathy taught it that many diseases would get well without medicine; but it has abandoned bloodletting almost entirely. It appears to be a simple assumption, unsupported by sufficient reasons, to say that in this abandonment the pendulum has swung too far to one side.

Dr. Hubbard had bled in every case of puerperal convulsions that had come under his hands. He had seen its good effects in convulsions, both ante- and post-partum, and he should use it in both. He related a case of a stout primipara, whom he saw for the first time when called to deliver her. He found her sitting up, with face flushed and pulse full and bounding. These symptoms showed plethora, and he at once proposed to bleed her; but the woman stoutly refused. She soon went to bed, and the labor progressed favorably for a time; but his fears were verified when, as the head was pressing on the perinæum, she went into a convulsion. Then he practised free bleeding, followed by a dose of calomel and Dover's powder; delivered with forceps; and she did well. In another case of a delicate, and by no means plethoric, primipara, twenty-two or three years old, the labor had favorably terminated, although the amount of hæmorrhage was pretty large for so delicate a subject. Convulsions came on sixteen hours after delivery. He bled her a pint, and put her slightly under chloroform, when the convulsions yielded for a while, but came on again. Then he gave calomel and Dover's powder, with infusion of digitalis (a suggestion of the late Dr. Batchelder); kept up the chloroform; and in the morning, when the calomel had moved the bowels, the trouble was over. He thought a great deal of moving the bowels. In this case, although the convulsion occurred so long after labor, the patient had no recollection of his having attended her; and this lapse of memory was characteristic of all the cases he had seen. He was not one of those who had ceased to bleed in these cases, in obedience to the dictates of homœopathy or anything else.

Dr. Prince was one of the favored few who had seen both extremes of practice. As hospital-walker he had had to carry his lancet, and be ready to use it in the lying-in, as well as in the general, wards. He had certainly seen benefit from it in many cases, and he was prepared to endorse to the full everything Dr. Barker had said. In convulsions he had seen morphine fail to produce the slightest relaxation of their violence, and even chloroform, though often giving happy results, could not be depended upon in every case. In his own experience bloodletting had proved more efficacious than any other treatment. It was essential to use great care in the selection of cases for its employment, and closely to watch the effect produced during the flow. If the patient showed returning consciousness and general improvement, that was a sign that your remedy was doing good.

Dr. Austin Flint, Senr.—I came here to-night thinking that, as the topic related to midwifery, and it was well known that I was not specially devoted to that branch, I might have the privilege of remaining a silent listener; but I have no right to refuse the President's call. The paper of my friend, Dr. Barker, seems to me significant not only of the change in the views of treatment of diseases connected with pregnancy, of which I, perhaps, cannot well judge, but of the change of view with regard to the treatment of diseases unrelated thereto. I can go back, as other speakers have done to the time when bloodletting was very freely and, very indiscriminately employed; when it would have been considered malpractice to allow any acute inflammation, and many even of the chronic inflammations, to go wtihout more or less abstraction of blood. At that time to bleed in inflammation was a received maxim. I recollect even hearing it said, "When you are in doubt whether to bleed or not, use the lance; give the patient the benefit of the doubt"! We can see now that this mode of employing booldletting was frequently injurious, often, indeed, exceedingly so. There comes to my mind, at this moment, a case of puerperal fever in which, after consultation with two much older men, I practised venesection only a very short time before death. Under the circumstances where it was then employed, this measure would now be considered almost murderous.

The question that has been raised to-night is certainly pertinent, whether the great change that has occurred since that time is merely the oscillation of the pendulum to the other extreme, or is a real advance, not to be followed by reaction. I think it is easy to see the processes by which this change has been wrought. The effect of bloodletting on the circulation and on the constitution of the blood was studied by Gouch, Marshall Hall, and others; and it was proved that the abstraction of blood aggravates some of the very conditions which were regarded as indications for its employment. The more thorough study of the blood in certain morbid conditions gave us the key to their pathology. Before this, anæmia, for instance, was not known to consist in a diminution of the red corpuscles. Above all, the profession came to see more and more the importance of knowing the natural history of diseases—their progress uninfluenced by any active medication; and, as this study was prosecuted, it was found that diseases, which it was supposed would, left untreated, almost certainly prove fatal, in reality tended intrinsically to a favorable termination. I am not disposed to give the homœopathists the credit of this. We are indebted for it to the conscientious study of the men in our own profession.

I found myself, in the early part of my professional life, an opponent of bloodletting. One of my youth-

ful essays was directed against it. I have found myself, for the last few years, an advocate of bloodletting to a certain extent; and have ventured the prediction that not many years will elapse before we shall again find the profession practising it, though in a very different way from our predecessors. I feel surer of nothing than of this. The lancet is again to find its place in our armamentarium; and it becomes a question of the greatest import, as we resume its use, What are the indications for it, what its contra-indications? This opens up a great subject, to which, of course, I can do no justice to-night. But I think this is a sound principle applicable to this case as well as to others: The opinions of those who have preceded us, where they have been generally held, and for a long time, we have a right to assume cannot be altogether without some basis of truth. Therefore, although every one, who has had the opportunity of observing both past and present practice, cannot fail to admit that much harm was done by indiscriminate and excessive bleeding heretofore, still it would be very unphilosophical to put aside all the former experience as worthless. So, too, with regard to other remedies, mercury for instance; and I venture to predict that before many years we shall find mercury again held more highly in esteem.

The indications and contra-indications for bloodletting I cannot attempt to discuss in these desultory remarks. One of the great advantages which it has over other measures, by which similar or the same effects may be accomplished, is its promptness of action. We can produce certain effects on the pulse, etc., in a few moments with veratrum viride, and with other remedies—effects very similar to those of venesection, except that some time must elapse before their appearance. But there are cases—cases of uræmic coma, for example—in which moments are very precious; and it is these cases which will lead to venesection again becoming an effective measure in our practice. What will it do? The practitioners of twenty years ago believed, with great confidence, that the abstraction of blood would sometimes arrest inflammation. I believe that it will sometimes arrest it. I believe that, in the last two years, I have seen two cases of pneumonia arrested by bleeding. They were cases in Bellevue Hospital; and the diagnosis was based upon physical signs, and was not to be questioned. Doubtless the value of this method of antiphlogistic treatment was formerly over-estimated; but I think it has great value, and that we may employ it in acute inflammation if there are no contra-indications. Those practitioners believed that, if it did not arrest inflammation, it would shorten the period of its duration. I believe it will do this; and I think it a matter of therapeutic importance of which we may avail ourselves except where there are contra-indications, where there is a tendency to exhaustion. In my lectures upon pneumonia, last winter, I opened the subject of treatment by reciting a case from my own practice, which I reported thirty years ago. This case was treated by bloodletting, a moderate amount of mercury, and some tartarized antimony. The duration of the disease was eight days, I believe. I cited it as a good example of successful treatment thirty years ago.

I spoke of one contra-indication, the tendency of a disease to destroy life by asthenia. Bloodletting could only increase this tendency. But where a disease is likely to prove fatal by apnœa, the case is very different. I happen to be now lecturing upon acute laryngitis. Here is a disease which is very apt to destroy life if surgical interference is not resorted to—which may destroy it in a few hours. The danger is not at all from exhaustion; it is from apnœa, and it becomes important to bring to bear every measure which gives any hope of relief. I advocated to my class, as strongly as I could, prompt, energetic bloodletting. So, *mutatis mutandis*, with apoplexy and insolation. There are some chest diseases where, by diminishing the quantity of blood, we diminish the amount of labor inflamed parts have to perform. I may mention that twice in my life I have myself experienced the immediate and delightful relief afforded by bloodletting in an inflammatory affection of the smaller bronchial tubes. This relief was so prompt and so marked, after other measures had been tried for a day or so without avail, that I can never forget it.

It was a striking incident that Dr. Barker could not obtain a lancet at the instrument-maker's. Striking, too, was the remark by one of the gentlemen who preceded me, that he had never, in fifteen years' experience, seen a venesection. It is not long ago that there was admitted to my service in Bellevue Hospital a case of insolation in which it seemed to me that bloodletting was appropriate. The house-physician was asked to bleed the patient, and replied that he would do so with pleasure, but he had never seen the thing done, and did not know exactly how to go to work; and I soon saw that he did not. Those of us who practised in the bloodletting times used to deem it a very essential accomplishment to be able to bleed well; to apply the ligature with just the requisite tightness; to get the stream of the right size, and in the right direction; by no means to allow it to spurt in the physician's face or over the bed. After what we have heard to-night, I am almost tempted, though I fear it might be hardly decorous, to call on those gentlemen who have lancets in their pockets to show them.

The President was requested to give his views, and remarked:

We have learned to our satisfaction that it would be a great mistake to abstain from venesection as an invariable rule, just as it would be a great mistake to resort to it too frequently. I do not know whether it has been the habit of many physicians not to have recourse to it at all; I know that I very seldom perform it, but now and then deem it indispensable—sometimes once in two, three, four years, sometimes twice or three times in half a year. I will briefly state the indications I have followed. Not a single disease has been named here to-night, or a single class of diseases, in which venesection should be resorted to, with the exception of one class of inflammations mentioned by Dr. Flint. That by venesection inflammation can be prevented or cut short in the first stage, I believe is true; because it acts to remove one of the requisites for inflammation, that is, dilatation of the blood-vessels, local congestion. Inflammation as such, that is, the new formation of cells, and of fibres out of the cells, will not be influenced by venesection; but the local hyperæmia will be so influenced, simply because it relieves the blood-vessel pressure; and so I imagine that local inflammation may be benefited by bloodletting.

This mechanical action in relieving the blood-pressure, makes it of inestimable use in meeting another class of symptoms (not of diseases). For instance, I am quite positive that many a case of pulmonary œdema will die without prompt venesection. I have seen such cases; and have performed venesection myself where I was certain that the patient would have been dead in fifteen minutes but for that. But pulmonary œdema is not a disease; it is a symptom

which may appear in the course of a number of diseases. We see it after fevers, scarlet fever and others. We see it in the same degree, and presenting the same danger, in acute pneumonia. There it takes place from the rush of blood to the lungs in overwhelming quantity; its stagnation from the obstacle to its passage through them; and effusion as a consequence. Pulmonary œdema, then, is only a symptom, which may be developed in fever, pneumonia, etc. We treat this symptom by venesection, simply to relieve the blood-vessel pressure, prevent further serous effusion, and allow absorption of that which has taken place. We do not treat the disease itself by venesection; indeed, when we find pulmonary œdema coming on, we do not stop to diagnosticate the disease which has caused it; we have no time for that. We only know that the patient is suffocating from the filling up of the air-vesicles and bronchial tubes, and that if anything will relieve this, it is venesection; so we open a vein at once, and consider the diagnosis afterwards.

The same holds true of œdema of the brain. No matter whether this is the result of local disease, as, for example, apoplexy with consecutive inflammation, or of an essential fever, we shall in all probability, as soon as we are satisfied there is œdema, first draw blood and relieve the patient, then look for the diagnosis.

The indication in all these cases is a vital one. We cannot ask ourselves what will become of the patient next week? How pale will she look? How long require for convalescence? We can only ask, Will this patient live for half an hour if I do not resort to venesection? The symptomatic indication is thus fulfilled, and in most cases we shall afterwards have time to decide what shall be done to relieve not only the previous general anæmia, but also the added trouble brought on by our enforced interference. So in all the cases mentioned by Dr. Barker, I believe we are to resort to venesection simply to save the life of the patient.

I would attempt to answer one question which has been put to-night: What is the difference between that œdema of the brain which we see in cases of fever, pneumonia, etc., and that œdema which we see in the cases that have been called, by Marshall Hall and others, cases of hydrencephaloid disease? I think the difference a vital one with reference to treatment; therefore it is important to make the diagnosis. In hydrencephaloid disease we have more or less chronic exhaustion. We seldom see a case except there has been some exhausting disease at work, for one day, one week, six weeks. Under this the brain gets emaciated just as do fat and muscle. It is no longer large enough to fill the intra-cranial space, and effusion must take place. We have effusion into the brain-substance, and into the arachnoid sac, so-called, or, as I prefer to say, arachnoid tissue. We learn, then, from the history of the case, that there has been chronic pneumonia, intestinal catarrh, or longer continued chronic diarrhœa, etc., and in such a case we ought not to resort to bloodletting. But where we have to deal with acute œdema, we have no such history of exhausting disease. We find simply an acute disease, as a fever, which we may perhaps diagnosticate at the moment, or may not. When we see dilated pupils, flushed face, delirium, we are not to consider, Has this poor woman been anæmic before, and are we not in danger of rendering her more so? but, Can she live in this way four hours? No matter how she may look in six weeks, we shall be satisfied if we have saved her life.

On motion of Dr. Chadsey, it was voted that, as the first Monday in January, proximo, will be the day devoted to New-Year's festivities, the next regular meeting be held on the second Monday in that month.

The President announced that, at the next regular meeting (January 9th), Dr. Knapp would read a paper upon bone-formation in the eye; and that, at the regular meeting following (February 6th), a paper would be read by Dr. Austin Flint, Senior.

The meeting adjourned.

Correspondence.

THE DUTIES OF PHYSICIANS IN CASES OF DEATH, ETC.

BUREAU OF RECORDS OF VITAL STATISTICS, HEALTH DEPARTMENT OF THE CITY OF NEW YORK.

NEW YORK, JANUARY 5TH, 1871.

TO THE EDITOR OF THE MEDICAL RECORD.

I DESIRE to occupy a small space in your columns in order that I may explain to physicians their duties in cases of death, as finally determined by this Department.

Sec. 167 of the Sanitary Code, which lately required *all* deaths to be reported within 24 hours, was amended by the Board on Dec. 28th, last, and now reads as follows:

"Sec. 167. It shall be the duty of each and every practising physician in the city of New York to report in writing to the Board of Health the death of any of his patients who shall have died in said city of contagious or infectious disease, within twenty-four hours thereafter, and to state in such report the specific name and type of such disease."

The diseases referred to by the above ordinance are defined in Sec. 5 of the Sanitary Code to be: Cholera, yellow fever, small-pox, diphtheria, typhus, typhoid, spotted, relapsing, and scarlet fevers, as well as "any new disease of an infectious, contagious, or pestilential nature, and also any other disease publicly declared by this Board dangerous to the public health."

The above-mentioned reports will be made upon special blanks which are about to be distributed among the profession. In *such cases*, however, as well as in *all other* cases of death, the usual "Certificate of Death" must be filled out and be deposited in this Bureau within *thirty-six hours* after death (Sec. 150 of Sanitary Code), upon the responsibility of the attending physician.

Very respectfully,
Your obedient servant,
CHAS. P. RUSSEL, M.D.,
Reg. of Records.

ARMY AND NAVY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department United States Army, from December 18, 1870, *to January* 3, 1871, *inclusive.*

HASSON, A. B., Surgeon.—By S. O. 272, c.s. Headquarters Department of the South, granted leave of absence for 30 days,

MCELDERRY, H., Assistant Surgeon.—By S. O. 162, c.s. Headquarters Department of Texas, relieved from special quarantine duty and ordered to Fort McIntosh, Texas, for duty as Post Surgeon.

BENTLEY, E., Assistant Surgeon.—By S. O. 368, A. G. O., December 20th, 1870: leave of absence extended 30 days.

Dickson, Jno. M., Assistant Surgeon.—By S. O. 121, c.s. Headquarters Military Division of the Missouri, leave of absence extended 30 days.

O'Reilley, R. M., Assistant Surgeon.—By S. O. 385, A. G. O., December 31st, 1870: relieved from duty in the Department of California, and to report to the Commanding General Department of the Platte for assignment to duty.

Storrow, S. A., Assistant Surgeon.—By S. O. 268, c. s. Headquarters Department of the South, granted 30 days' leave of absence.

Medical Items and News.

Contagious Diseases—Vaccination.—Dr. Moreau Morris, City Sanitary Inspector, makes the following report to the Board of Health, January 4, 1870:—

In presenting the report upon contagious diseases to the Board, I beg leave to call attention to the fact that there is a slight increase in the number of cases of small-pox, as reported to this Bureau during the past fortnight.

In the knowledge of this even slight increase, with the fact of there being considerable of this disease closely adjacent to the city, which by constant intercourse may be easily communicated to our population, I cannot but feel that we are admonished to adopt such precautionary measures as will secure the greatest protection. These are vaccination and revaccination. By making known the danger, the public will be urged to apply to the proper places for these means of protection.

To the poor this boon is offered gratuitously at all the city Dispensaries; and with those pecuniarily able to employ medical assistance, there is no difficulty to be found in applying the precaution.

The season for the next four months is propitious for this operation; and therefore the neglect is the more inexcusable.

Again, I would urge this matter upon public attention, as well as that of the Board, for the reason that there is much danger of becoming infected in the promiscuous travelling in street cars and omnibuses in the city. It not unfrequently comes to the knowledge of this Bureau that persons in various stages of small-pox do use these conveyances going from point to point in this city—two such cases occurred during the past week.

As vaccination is the only sure prophylactic against this loathsome and fatal disease, a sense of duty compels me by every legitimate means to arouse the public mind to the danger of neglecting this simple precautionary measure. All, young and old, should be protected by it. A compulsory vaccination by law would almost secure immunity from this disease.

The following table exhibits the movements of contagious diseases in the city during the past two weeks ending Saturday, Dec. 31, 1870:—

Week Ending	Fever. Typhus.	Fever. Typhoid	Fever. Relapsing.	Small-pox.	Scarlatina.	Measles.	Diphtheria.
Dec. 24.	3	19	5	6	54	64	13
Dec. 31.	1	7	4	7	85	88	8

Respectfully submitted,

Moreau Morris, M.D.,
City San. Inspector.

Medical Library and Journal Association of New York.—This is the changed name of the New York Medical Journal Association, adopted at its annual meeting, Dec. 6, 1870, when also its constitution was otherwise amended, and the following officers were elected: *President*, Dr. Samuel T. Hubbard; *First Vice-President*, Dr. Alfred Underhill; *Second Vice-President*, Dr. Edmund R. Peaslee; *Recording Secretary*, Dr. F. A. Burrall; *Corresponding Secretary*, Dr. Emil Noeggerath; *Treasurer*, Dr. Horace P. Farnham; *Librarian*, Dr. Alfred E. M. Purdy; *Trustees, to serve for three years*, Drs. Isaac E. Taylor, Henry D. Noyes, Frank H. Hamilton, Cornelius R. Agnew, Alfred C. Post; *Trustee, to fill vacancy*, Dr. E. S. F. Arnold.

Rhode Island Medical Society.—The quarterly meeting of this society was held at Providence, R. I., Dec. 23, Dr. Geo. L. Collins, of Providence, President, in the chair. An interesting paper on the use of alcohol was read by Dr. Garvin, of Lonsdale, and freely discussed, the sentiment being adverse to its indiscriminate use as a remedial agent. Among other papers worthy of notice we might mention one by Dr. Ballou, of Woonsocket, entitled "Recollections of Scarlatina," as presented in a practice of 38 years, and one on the "Claims of Clinical Medicine as an Independent Science," by Dr. C. O'Leary, of Providence.

An Experience Larger than Jenner's.—Dr. J. P. Loines, of New York, vaccine-physician to the chief dispensary of that city, in bearing testimony to the immense services and complete harmlessness of vaccination, is able to refer to a public and authenticated experience for the past sixteen years, in the vaccination and protection from small-pox, even in periods of epidemic and constant contact with the disease, of about 300,000 persons, with humanized lymph from more than 40,000 infants. He has distributed more than 1,000,000 charges of vaccine lymph to about 3,000 different physicians. In no one instance has he received any complaint of injury or of failure of its product in true prophylaxis.—*British Med. Journal.*

Sulphurous Acid in Typhoid Fever.—Dr. Wilkes, of Ashford, Kent, affirms that he has had *very great success* in the treatment of typhoid fever by means of small doses of sulphurous acid. He gives the acid, with syrup of oranges, in water, in doses of from two and a half to twenty minims every four hours, until the patient complains of tasting, as it were, lucifer matches. He alleges that this remedy arrests the further development of the fever-poison, and thus *exterminates* the fever. "Briefly, it is an antidote." Of 173 cases of typhoid fever treated, only two died, and these two did not take the acid.—*Med. Press and Circular.*

A Large Dose of Chloral.—The poisonous dose of hydrate of chloral has been accidentally tested recently in a London hospital. A patient received in mistake 160 grains of the agent, and recovered, with little other effect than a very prolonged sleep.—*Med. Press and Circular.*

Army Medical Museum, Washington, D.C.—This collection includes 897 human crania, and 34 skeletons. A larger number of skulls from tumuli, and of crania of North American Indians, are found here than elsewhere. In the standard systematic work on surgery, by Billroth and Von Pitha, in the last edition of the English System of Surgery by Holmes, in Didiot's "Service de Santé des Armées," and in nearly all works on military medicine and surgery printed in the last five years, the majority of the wood-cuts are derived from the specimens in the United States Army Medical Museum.

Cases of Ectopia Cordis.—Dr. Henry Tuck, Boston, Mass. [(*Boston Med. and Surg. Journal*), in his translation of the proceedings of the Berlin Medical Society, alludes to a rare case of uncomplicated ectopia cordis in an infant—reported by Dr. Neumann Schlesinger—which lived only a few minutes after delivery. The heart lay entirely free upon the centre of the sternum, horizontally across the body, its base towards the left, and its somewhat rounded apex towards the right. It had no pericardium. The *post-mortem*, made by Prof. Virchow, showed a patent foramen ovale and a defect in the septum ventriculorum.

In closing, he remarks that the interior displacement of the heart entirely outside of the walls of the thorax, without any complication or other deformity, is very rare. There have been found only six cases of this sort on record. The first, observed by Martinez, in Madrid, in 1706; the second, by Büttner, in Königsberg, in 1745; the other four by Sandifort, Haan, Albers, Monod, and Cruveilhier.

Chloride of Potassium.—In the salt deposits which underlie the variegated sandstone of Stassfurt, Prussia, a mass of carnalite—a double chloride of potassium and magnesium—has been discovered, equal to 6,000,000 tons of chloride of potassium. Large quantities of this deposit, amounting to 150,000 tons in 1866, are worked into chloride of potassium. From 20,000 to 30,000 tons of 82 per cent. chloride are now annually produced in this locality, and find ready sale at about forty dollars per ton.

Death of a Philadelphia Surgeon.—Dr. J. Rhea Barton, one of Philadelphia's most eminent surgeons, died January 2, aged 76 years.

The Philosophy of Chills and Fever.—In a review of Dr. Salisbury's theory of intermittent fever by Dr. John W. Weir, Edwardsville, Ill. (*Boston Med. and Surg. Journal*), the philosophy of chills and fevers is thus laid down.

A person exerts himself during a warm day; a cold wind comes on, or night-fall, while he is in a profuse perspiration, and without nourishing food or additional clothing he loses a large supply of animal heat. This is repeated daily for a time; the extremities of the exposed person become cold, he loses vitality, his heart beats feebly, and he sinks into a chill; he is *really dying*, and if there is not vital power enough left, death ensues; if life continues, however, a series of phenomena take place, which, by appropriate treatment, may result in recovery. He does not believe that intermittent fever is produced by any miasmatic poison; but is the result of sudden and repeated draughts of animal heat from the system, which feeble persons can prevent only by suitable clothing, nourishment, and tonics.

A War Victim.—We regret to hear of the death, at Versailles, of Dr. Brewster, an American dentist, who long practised in Paris, and attended many of the crowned heads of Europe. A few years ago he retired in favor of Dr. Evans, and took up his residence at Versailles, where, notwithstanding the American flag floating over his house, a number of Prussian officers were quartered upon him. Dr. Brewster died on Thursday, Dec. 15th, in a fit, doubtless brought on by the excitement and trouble in which he has been living for the last few months.—*Lancet.*

Death of a Noted Southern Physician.—Dr. R. B. Wellford, a prominent physician, and for many years a Professor of Materia Medica in the Virginia Medical Colleges, died Dec. 29th, in Richmond, aged 74.

Dr. Ricord.—In the terrible sortie of November the 30th, the most distinguished services to the wounded were rendered by Dr. Ricord. Having established his head-quarters in a ruined hut, he awaited the arrival of the *brancards* with their unhappy freight. As each poor sufferer was brought in, he gently but rapidly relieved him of his clothes, dressed his wound, or applied the splint to his shattered limb, as the case might be, placed him on his shelf, and had him conveyed by ambulance wagon to the steamers which were moored on the Marne, by Joinville. As soon as the boat had taken in as many as it could hold, it steamed swiftly down stream to the bridge near the Bastile, whence the *brancards* bore the patients to the hospitals or to the private houses which had been prepared for their reception. For hours and hours Dr. Ricord continued thus to exert himself. According to one eye-witness, he "created amazement by his ubiquity." The doctor's seventieth birthday was on the 10th of this month; and in the energy he displayed he adds another to the list of able and vigorous septuagenarians on whose prolonged career of usefulness we lately commented.—*Lancet.*

A Victim to Folly.—It is a melancholy fact, which should however be recorded, that the lamented Dr. Davis, who did such good service in Eastern France, and died at his post from small-pox, had never been vaccinated. He entertained a strong prejudice against the system, which he had expressed on more than one occasion. On his death-bed, when it was unfortunately too late, he did not conceal his regret that he had not submitted to the operation.—*Lancet.*

American Association for the Cure of Inebriates.—This association met for organization in New York City, November 30th, 1870, at Association Building, and made the following declaration of their principles:—1st. Intemperance is a disease. 2d. It is curable in the same sense as other diseases are. 3d. Its primary cause is a constitutional susceptibility to the alcoholic impression. 4th. This constitutional tendency may be inherited or acquired. 5th. Alcohol has its true place in the arts and sciences. It is valuable as a remedy, and, like other remedies, may be abused. In excessive quantities it is a poison, and always acts as such when it produces inebriety. 6th. All other methods hitherto employed having proved inefficient for the purpose of the cure of inebriates, the establishment of asylums is therefore the great demand of the age. 7th. Every large city should have its local or temporary home for inebriates, and every State one or more asylums for the more permanent cure and management of such persons. 8th. The law should recognize intemperance as a disease, and provide other means for its management than fines, station-houses, and jails.

The following officers were elected for the ensuing year:—*President*, Dr. Willard Parker, of New York; *Vice-Presidents*, C. J. Hull, of Chicago, and Hon. Otis Clapp, of Boston; *Secretary*, Dr Joseph Parish, of Media, Penn.; *Treasurer*, Dr. T. L. Mason, of Brooklyn, L. I.

Leprosy of the Bible, or Elephantiasis Græcorum.—The earliest records of the Greek elephant disease in Great Britain are those of the Welsh King, Hod Dha, in the year 950. It is said that King Henry IV., of England; Baldwin IV., King of Jerusalem; and King Robert the Bruce died of it. India is the present great home for leprosy, and in some parts of it *one out of every sixteen people* is affected with leprosy. The first complete work on leprosy has been written by Drs. Danielssen and Pocck, of Norway.

ASSOCIATION FOR THE RELIEF OF RESPECTABLE AGED INDIGENT FEMALES.—The fifty-seventh annual meeting of this benevolent institution was held at the Asylum, 226 East Twentieth Street, Dec. 1st, 1870. There are about 90 old ladies now living in the building. That portion of the Annual Report interesting to medical practitioners and statisticians is the fact that during the intense and long-continued heat of the past summer months, *ten* of the feeblest ones sank beneath the fell destroyer's blow—being over 11 per cent. of the whole. On one day three lay dead beneath its roof awaiting burial. The effect of the heat upon the whole household was great prostration of the vital powers; and although the best medical advice was had, and the kindest and the most careful nursing was given, these *ten* could not be made to rally.

The ages of those who died during the year (12), were as follows:—62, 63, 68, 71, 75, 82, 82, 82, 80, 84, 85, and 87.

The *Attending Physicians* are, Drs. W. B. Bibbins and Frederick A. Burrall; *Consulting Surgeon*, Dr. A. C. Post; *Consulting Physician*, Dr. E. R. Peaslee.

A CURE FOR LOVE MELANCHOLY.—Dr. James Ferrard, of Oxford, in 1640, published the following treatment for *love melancholy:* "The regimen, or order of diet, in cure of love melancholy, differs not at all from that that is to be observed in the prevention of it, save only that it ought to be somewhat more humectative and less refrigative; not forgetting, in the meantime, those meats that by some certaine occult properties they have in them, are found to be very good for those that are sick of this disease; as the turtle-dove, the heart of a wolfe, young owles taken and boyled in the juyce of marioram, the flesh of rats, and the like. And if the party be fallen away in his body, and is now grown very thin and dry, you must then prescribe him the same order of diet, according to Avicen, as you doe to those that are hecticall."

RELAPSING FEVER IN PHILADELPHIA.—John S. Parry, M.D., of Philadelphia (*Am. Journ. Med. Sciences*), publishes the history of 37 cases of this fever, occurring in Philadelphia, in the winter of 1869–70. He opposes the opinion that relapsing fever is largely due to starvation; but believes that a much more potent cause there was overcrowding, and the notoriously small breathing space allotted to each individual in the houses of the poor.

BOTANY AND ZOOLOGY IN MEDICAL STUDY.—Prof. Huxley, an examiner of the London University, complains that the knowledge exhibited by candidates for degrees in medicine is not precise or practical; and he partly attributes this to what he terms the "injudicious tests" applied at examinations for medical diplomas. Prof. Huxley would abolish botany and zoology in medical study, and make them subjects of general education; *materia medica* he would not teach, on the ground that it is as useless to teach a man where drugs come from, because he is a medical man, as it would be to put a man to the manufacture of steel, because as surgeon he would be called upon to use a knife; and comparative anatomy he would abrogate altogether.

"HUNT'S CEMENT" FOR SEALING EDGES OF THIN GLASS.—Dr. Joseph G. Richardson, of Philadelphia, in his "Handbook on Medical Microscopy," gives Hunt's formula for a cement, which is used for sealing the edges of the thin glass in the Army Medical Museum. It is prepared by evaporating Canada balsam to a solid consistence, dissolving it in an equal bulk of benzole, and then thickening it to about the density of cream, with white lead or zinc ground in oil.

THE VITALITY OF JENNERIAN VACCINE LYMPH.—According to M. Melsens, Jennerian vaccine lymph, exposed for an hour to artificially obtained cold of 80°, was found to have preserved its vitality.

VACCINATION FROM KINE.—The great importance of the question of vaccinal syphilis, which has perhaps been intemperately urged in some quarters, but which cannot yet be said to be definitely settled, renders it highly desirable that there should be furnished to the general practitioner some reliable guarantee against a repetition of the unfortunate occurrences which have given rise to the question. Such a guarantee would seem to exist in the use of *non-humanized vaccine.* Heretofore, the impossibility of obtaining such virus, except in rare instances, has stood in the way of its general adoption. We can now state, however, that through the enterprise of Dr. Henry A. Martin, of Boston, who has propagated, through calves, vaccine direct from the Beaugency stock, this difficulty is at last overcome. It will be gratifying to the members of the society to know that a supply of non-humanized virus, from the same source, is now kept up in New York, by a series of inoculations on healthy calves, by Dr. Frank P. Foster of the New York Dispensary.

A MARBLE BUST PLACED IN MEATH HOSPITAL, DUBLIN.—According to the *Canada Medical Journal*, a marble bust of the late Maurice H. Collis, M.D., has been placed in this hospital, where he was one of the distinguished surgeons.

KRYPTOPHANIC ACID.—Dr. Thudicum (*Med. Times and Gazette*) announces that he has discovered a normal free acid in the healthy urine, which he styles *kryptophanic acid.*

THE ORIGIN OF SPECTACLES.—Thomas J. Bowditch (*Troy Times*) finds the earliest record of the use of spectacles is in 1703. According to the *Florence Illustrated*, the first inventor of spectacles was Salvino Armato d'Armati, in 1713. But this is evidently a mistake. Mr. Bowditch may see in some of the Italian galleries an ancient painting of the adoration of the Magi, in which one of the wise men is looking at the Holy Child through a veritable spectacle.

THE LEECH TRADE.—France has consumed annually 100,000,000 leeches; England and Germany the same, and other countries in proportion. The prime cost of leeches sold in Europe exceeds £2,000,000 per annum. Some parts of Australia abound with leeches, those which frequent the Murray River being preferred to any other specimen. They bite freely and leave no inflammatory wound or mark behind; they surpass the famed freckled leeches of Northern Europe.—*Melbourne Argus.*

THE PULSE.—The pulse was first noticed by Galen. It is slower in the inhabitant of the country than in one of the city. In the West Indies it is 100; in Greenland as slow as 40; and is slowest in the cold climates. It is slower in the winter than in summer. Is slow in the morning, quick at noon, and more frequent at night.—*Med. and Surg. Reporter.*

THE ORIGINATOR OF PATHOLOGICAL ANATOMY.—About three centuries before the Christian era, Herophilus, a native of Chalcedon, and Erasistratus, of Iulis, a grandson of Aristotle, laid the foundation-stones of the science of human anatomy. Herophilus, it has been said, resorted to human vivisections, more particularly of criminals. He was the originator of pathological anatomy, and was the first to propose post-mortem examination to learn the cause of death. Fallopius, centuries after, denominated him "the evangelist of anatomists."—*Dr. Gouvr. M. Smith's Discourse.*

Pneumonitis.—So far as published statistics can be relied on, the mortality of pneumonitis varies, under different modes of treatment, from one in two and a half (by Rasori's) to one in thirty-two (by Bennett's). In England seventeen per cent. of the deaths are said to be caused by pneumonia, and in this country its death-rate is thought to be still higher.

Polypus of the Rectum.—In 1816, Delpech, for the first time, described polypus as a distinct affection of the rectum.

Hereditary Twin-bearing Family.—Dr. Curgenven (*Trans. Obstetrical Soc.* of London) attended a lady who was delivered of twins for the fourth time; she had severe flooding, and barely escaped with her life. This was her sixteenth conception during a married life of 16 years. Her mother had twins once, her aunt once, and her great-grandmother twice.

Perils of Epicures.—Those fascinating little foreign cheeses which make their appearance in foreign and fashionable provision stores, wrapped in tinfoil, are not, it seems, as safe as they are, to some people, attractive. The tinfoil contains lead; and the lactic acid of the cheese, favored by the condition of moisture, leads to contamination of the outer layers especially with that poisonous metal. Soap, chocolate, and dry confectionery, so largely wrapped in the foil, were found, on recent examination by Augustus Vogel, to be quite free from contamination.—*British Med. Journal.*

The Monomaniac.—Although it is claimed by most writers on mental diseases that the mind of the *monomaniac* is sound, apart from his delusions, Dr. Chas. A. Lee holds that the diseased idea is a part of the mind; and that the mind, therefore, is no more sound than the body is sound, when a man has a serious disease of some vital organ—that the exquisitely delicate and complex mechanism of mental action, the brain, is radically deranged; else, the morbid idea could not have been engendered and exist.

Improved Instruction of Deaf-Mutes.—In 1867 the "Institution for the Improved Instruction of Deaf-Mutes," or the German method, was established in New York City, at No. 330 East Fourteenth Street. The school is under the superintendency of Mr. F. A. Rising, A.M., assisted by Misses Stevens and Hubbard. Its objects are to teach deaf-mute children (whether congenitally deaf or from disease in infancy) and semi-mutes to use articulated sounds instead of the manual alphabet or the sign language. The institution opened with seven pupils; in 1868 there were twenty-three pupils, and during the year 1869 there were thirty-two. The State donated it the sum of $10,000 at the last session of the legislature. The officers are as follows: President, Mark Blumenthal, M.D.; Vice-President, L. J. Phillips; Treasurer, Isaac Rosenfeld; Secretary, Jacob Rothschild; and eleven trustees. This system of educating deaf-mutes is being introduced in Chicago, Illinois, by David Greenberger, Ph.D., and almost all parents of deaf-mutes in that city and the surrounding places avail themselves of the benefits of this school.

The Discovery of Coal-Tar Colors.—W. H. Perkin, F.R.S. (*American Chemist*), reminds us that aniline purple was discovered in 1856; three years afterward, in 1859, the Magenta was introduced; in 1861, the aniline blue; in 1863, the Hofmann violet; and in 1865, the Britannia violet. Thus we discover that all these colors have not only been discovered, but introduced, commercially, in a period of about ten years.

Sin the Supposed Cause of Disease.—According to W. A. P. Martin, D.D., LL.D., Professor of International Law in the University of Pekin (*Am. Practitioner*), disease is looked upon in China as a punishment for sin in this or a former life, and, therefore, the spirits who are supposed by heaven's permission to inflict these punishments by sending diseases must be appeased. The remark is often made by the Chinese that they are expiating their sin in their disease; that it is the just retribution of heaven. They are thus ever anxious and ready to resort to the temples to burn incense, to discover the fates, or appease the gods, and avert or remove some malady. The people have more faith in their *gods* than their *doctors*; for although they sometimes seek relief from their native physicians (if such they deserve to be called), yet they quite as often resort first to the temples. If the patient recovers it is attributed to the mercy of the god consulted; if he die, it is ascribed to fate. A large and increasing number from all classes, who find no relief from their idols and gods, come at last—often, alas! too late—to the foreign hospital.

Obstetrical Statistics.—N. H. Chesebrough, M.D., of Hoboken, N. J. (*Med. and Surg. Reporter*), records 2,740 obstetrical cases occurring during a period of 25 years. A large majority of these cases were attended by him in New York City and its immediate vicinity.

Excluding 52 cases in which the reports are meagre and insufficient, there remain 2,688, including twins (31 cases), 2,719 births: males, 1,411; females, 1,308. Of this number, 157 were still births: males, 83; females, 74. Of these latter, 61 were the product of abortion: males, 33; females 28; including 5 cases of twins.

The presentations were as follow: Of the head (vertex), 2,596; of the breech, 71; of the inferior extremities, 30; of the superior extremities, 15; of the face, 7; total, 2,719.

In the 31 twin cases the presentations resulted: Of the head, 34; of the breech, 16; of the feet, 8; of the arm, 4. There were 5 cases of placenta prævia births: males, 2; females, 3. Children all still-born.

Forceps were applied in 139 cases. Children born, 141 (including 2 cases twins): males, 83; females, 58. Of this number there were still-born: males, 11; females, 3.

There were retained placentæ in 26 cases, in 8 of which the placenta was more or less adherent, requiring manual interference for their removal. In no case did unfavorable results follow from this cause.

He also records one case each of hypospadias, umbilical hernia, spina bifida, club-hand, hydrocephalus.

Original Lectures.

THE FORMATION OF BONE IN THE EYE.

REMARKS BEFORE THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK, JAN. 9, 1871.

BY H. KNAPP, M.D.,

NEW YORK.

THE subject which I beg to introduce to your attention is partly of clinical interest and partly of pathological. In the eye, as you know, is represented nearly every tissue of the body except bone. Bone occurs, indeed, in the eyes of birds, in the sclerotic, where it seems to be a support for the ciliary muscle, which in birds is a striped muscle. Is it possible that true bone is ever formed within the human eye, if not under physiological, then under pathological, conditions? This question has been answered both in the affirmative and in the negative by good authorities. In former times very able and expert surgeons described cases of ossification of the interior of the eye minutely enough with regard to their microscopic appearance; and, later, Mackenzie and others published cases perfectly faithful to nature. But there came about a reaction in which the tendency prevailed to discredit these accounts, and to regard all the so-called ossifications within the eyeball as merely calcifications, lacking the corpuscles and nutrient canals characteristic of true bone. The literature of the subject is rather scanty, but an excellent paper was published in *Graefe's Archives*, in 1860, by Dr. Pagenstecher, who made his investigations in the laboratory and under the auspices of Prof. Heinrich Müller, who has done so much for ophthalmic pathology. This paper is based upon the examination of eight cases; it also collates the labors of previous investigators; and it establishes the occurrence of true bone in the eye beyond a doubt. In one of the cases the origin of the bone is clearly traced to the capillary layer of the choroid.

The fact of the occasional formation of bone in the eye being established, many other questions remain to be elucidated, some of which I may point out. 1. Which of the membranes, and which layer of each, are the starting-points of ossification? 2. What is the nature, the cause, and the extent of the ossific process? 3. What changes are produced by it in the membranes not undergoing ossification? 4. Can the affection be diagnosticated, and how? 5. What is its prognosis, and what its treatment? The answers to these questions must rest both upon clinical observations and upon pathological research. I may be allowed briefly to relate my own experience.

The first case which came under my notice was that of a girl, seventeen years of age, of scrofulous habit, subject to ophthalmia from earliest childhood. The left eye was exceedingly weak, and she had lost the sight of it three years before I saw her. At that time the right was also suffering, as it had often done, from sympathetic inflammation. There was great photophobia, and its visual power was failing, being found on examination to be only one-fourth the normal standard. The posterior part of the left globe was as hard as wood to the touch, its anterior third presenting the normal resistance. Since it was evident that the seeing eye was suffering from sympathy with the blind one, I complied with the patient's request to remove the latter. It disclosed a hard shell reaching from the optic entrance to the ora serrata. This shell had replaced the inner layers of the choroid. It was covered internally by a layer of connective tissue; and from the ora serrata, where the hard shell terminated, this connective-tissue layer was continued into a diaphragm which stretched across the vitreous chamber at a short distance behind the lens. The retina was completely detached from the choroid, being connected only with the optic nerve behind and the ciliary body in front, so that it floated in the vitreous as a funnel-shaped membrane. The hard shell proved, under the microscope, to be true bone.

This case set me thinking of the origin of ossification. I considered, as has been urged by others, that ossification is an active process, requiring a large supply of nutritive material, while calcification is a process of regressive metamorphosis, occurring in tissues which have ceased to grow and are undergoing atrophy or degeneration. Ossification, therefore, ought to start from that part of the eye where there is an abundant nutritive supply, and this condition is found only in the capillary layer of the choroid. The external layer of the choroid is extremely rich in blood-vessels, it is true, but they are not destined to its nutrition; it is certainly no better nourished than any other tissue having no peculiar function. It is the number of its *capillary* vessels which determines the dignity of an organ. Now it is a remarkable fact, brought out by the researches of Dr. Leber, that the capillary vessels of the choroid cease at the ora serrata, at the commencement of the pars plana corporis ciliaris. Ossification, in this case, extended just to this boundary; and just here the false membrane stretched across the vitreous chamber.

A physiological principle seemed here to be indicated by pathology; but a single case would prove nothing; it must be corroborated by others. Soon after this, my friend, Dr. Althof told me that he had observed a case in which the osseous plate lay in the anterior portion of the eye, the posterior part being entirely free from bony formation—a case just the reverse of my own. He was kind enough to lend me the specimen. Unfortunately it had passed through many hands, and of the posterior portion nothing remained but the sclerotic; the anterior portion, however, was well preserved. There was an ossified transverse septum extending across the globe behind the lens, from the edge of the ora serrata, leaving the lens and the parts in front of it entirely free from bone. The choroid, I was told, was also free from it. In this case, then, the ossification would seem to have started from the anterior edge of the chorio-capillaris. There was, doubtless, first inflammation of this portion of the capillary layer, resulting in plastic exudation, which, as it increased, had perforated the pigmentary layer and the hyaloid membrane, and streamed into the vitreous as a false membrane. This false membrane then became the site of true bony deposit, to which connective tissue is always liable when it is sufficiently nourished. The formation of bone in this case is, therefore, seen to be connected with the chorio-capillaris, and to constitute no exception to the physiological law above suggested.

Let us follow, for a moment, this process of bone-formation. There is inflammation of the capillary layer of the choroid, with plastic exudation. What does this mean? It means infiltration of the mother-tissue with lymphoid cells, that is, with white blood-corpuscles, together with transudation of blood-serum. Then their metamorphosis begins. The white blood-corpuscle, from being a wandering cell, is becoming a fixed cell. It soon acquires a larger protoplasmatic body, and stretches out offsets, which speedily communicate with the offsets of its neighbor-cells, that have ceased from their wanderings to found a colony here,

Thus there is formed a connective tissue of cells having between them protoplasm and nothing else. Only later, when the new tissue has become older, you find its intercellular substance exhibiting the fibrous character. By and by this intercellular substance gets impregnated with chalk, at first only slightly, afterwards more and more densely; and the denser this chalky infiltration, the more fixed do the included cells (white blood-corpuscles, connective-tissue corpuscles, soon to be bone-corpuscles) become, until the tissue is entirely stiff and their further movement impossible. In the specimen here shown you see the chalky intercellular substance forming a firm trabecular network, holding in its meshes the cells, which are not at all solidified. This kind of tissue, intermediate between connective tissue and fully developed bone, is called by Virchow *osteoid tissue.*

Dr. Althof kindly furnished me also two other specimens, but their condition did not admit of a complete examination. They showed only the osseous shell in the posterior part of the eye, evidently formed from the choroid. This shell was quite thick—in one of the specimens 2½ lines—and exhibited at the optic disc a round hole through which the retina passed to join the optic nerve.

For the opportunity of examining two other specimens, both well preserved, I am indebted to Dr. Reuling, of Baltimore. One of them was important as showing the ossific process in its beginning. A thin osseous, or rather osteoid, plate was forming in the connective tissue which had replaced the capillary layer of the choroid around the optic disc. Its inner surface was lined with connective tissue, while on its outer surface could be seen vessels from the outer layer of the choroid entering its nutrient canals. The anterior portion of this eye was quite remarkable. A section in the vertical meridian showed bone lying immediately behind the iris, beside the lens, giving the impression, at first, that the ossification must have started from the iris or the ciliary body. There would have been nothing improbable in this; for both the iris and the ciliary body are highly vascular; and we often see formed on the surface of the iris false membranes of connective tissue, liable, of course, to ossification. Closer examination showed, however, that the bone had started from the anterior part of the choriocapillaris, and had been drawn forward to its present position only by the contraction of a cicatrix, which had resulted from traumatic injury and included all the structures in the anterior portion of the globe. This was clearly proved by the fact that the layer of choroidal pigment-cells was found intact on the anterior surface of the bony plate. This case affords an explanation of one described by Pagenstecher as a curiosity which he could not understand. In his case the ossification had advanced somewhat further forward and toward the optic axis, coming in contact with the ciliary processes; and the plate of bone showed, impressed upon its outer and anterior surface, a cast of these forming a complete corona ciliaris. This impression of the ciliary processes must evidently have been made upon the bone while in its soft, formative condition; and it clearly shows that the ciliary processes were not themselves centres of the ossification. This first specimen of Dr. Reuling's, like the case first related, had, connected with the bony plate in the anterior part of the eye, a diaphragm of connective tissue, passing across the vitreous behind the lens, to which it was closely attached by the cicatrix above mentioned.

Dr. Reuling's second specimen brought out no additional points, but served to confirm those previously observed. It was also one of traumatic injury, and the foreign body, a piece of percussion-cap, was found encapsuled and suspended in the vitreous immediately behind the posterior pole of the lens. This is quite unusual; heavy foreign bodies entering the vitreous chamber commonly sink to the bottom of the globe.

The last case I have examined is that of the woman who sits before you. Nineteen years ago she had, in the left eye, what was probably an attack of acute iritis, which left the eye weak and its vision impaired. Seven years later both eyes were attacked, the left becoming blind, the right recovering. Since then there have been several accessions of inflammation in the blind eye, with which the right would sympathize. Some four months ago, in one of these attacks, the right eye suffered severely, and she came to the Ophthalmic Institute for relief. It showed the symptoms of grave irido-choroiditis; antiphlogistic treatment proved ineffectual; and enucleation of the left eye was performed, to remove the cause of the probably sympathetic inflammation in the other. Though the operation was done without accident, it has proved of less service than I had hoped, for the right eye has still continued subject to frequent exacerbations of the inflammation.

This eye, which the patient will allow you to examine, presents a typical example of irido-choroiditis. Sympathetic inflammation manifests itself under three forms: 1. Ordinary plastic iritis, which is easy to cure. When treated antiphlogistically, after removal of the other eye, it seldom relapses. 2. Serous iritis, in which a highly plastic exudation is deposited upon the posterior surface of the cornea, as well as upon the posterior wall of the anterior chamber. The affection is very chronic, and very prone to relapse and to bring on complications that may destroy vision—false membranes in the vitreous, cataract, shrinking of the globe, etc. 3. The form you see here—irido-choroiditis. You observe that the pupillary edge of the iris is completely bound down to the lens-capsule. The lens is somewhat opaque, and so is the vitreous body. This opacity of the vitreous, and the impairment of vision greater than could be explained by the iritis alone, indicate inflammation of the ciliary body and the choroid.

The left eye of this patient, before enucleation, presented the characteristic sign which makes it possible to diagnosticate ossification of the capillary layer of the choroid in the living subject—a wooden hardness of the posterior two-thirds of the globe, ceasing abruptly about two lines behind the margin of the cornea. Examining the eye after its removal, I found the evidences of active inflammation in the ciliary body and the iris, which accounted for the sympathetic inflammation of the other eye. Both these structures were thickened by a layer of lymphoid cells and of connective tissue already produced by their metamorphosis. The bony formation presented essentially the same conditions as those before described—an osseous shell occupying the seat of the inner layer of the choroid, covered within by fibrous tissue, and terminating at the ora serrata, whence a diaphragm of false membrane, beginning to ossify at its periphery, stretched across the vitreous.

These are all the specimens which have come under my observation, and reviewing them we come to the following conclusions:

The *origin of true bone* in the eye may always be traced to plastic inflammation of the capillary layer of the choroid. I find nothing in the literature to contradict this, though most of the cases are so ill reported as not to give the origin, sometimes not even the extent, of the ossification. Calcification may occur, and has been observed, in every tissue of the eye—it is found in several of the specimens we have examined to-night—but ossification only in connection with the very vascular

chorio-capillaris. In the retina the blood-vessels are scanty; in the lens there are none at all. Yet nearly every text-book speaks of osseous cataract. It may be correct, but it is in all probability erroneous. I have seen in old cataracts an unmistakable layer of fibrous connective tissue inside the lens capsule, and inside this layer a distinct calcareous deposit. But never have I found in this situation, nor has any one described or figured, a tissue having bone corpuscles, much less Haversian canals. The cases where ossification has been supposed to originate in the vitreous are probably to be explained by the extension into the vitreous of false membranes of connective tissue from the choroid, as in the cases we have seen, and their subsequent metamorphosis into bone. Of Pagenstecher's case of suspected ossification of the ciliary body we have given a rational solution.

The *nature of the ossific process* in the eye is the same as that in connective tissue generally, the same as in the formation of bone from periosteum. In the preparation under this microscope you can trace all the successive stages in the change of connective tissue into bone. The cells (white blood-corpuscles) and intercellular substance are poured out, the former in some places densely crowded; and then, with a clear line of demarcation, the infiltration with chalk begins. In some portions the connective-tissue corpuscles are still preserved round, or nearly so, having few offsets; but the more the chalky infiltration advances, the more numerous the offsets become, communicating with each other to form the canaliculi. The round, movable, lymphoid cell, putting forth its processes and retracting them again, becomes first the jagged cell of the osteoid tissue, and finally the stellate cell, the real bone-corpuscle.

What *changes* are produced by this process *in those parts* of the eye *not undergoing ossification?* The *retina* only exceptionally remains adherent to the bony shell —there is but one case on record. Commonly it is found contracted into a funnel-shape, having its apex at its attachment to the optic nerve, and its base at that to the ciliary body. Of course it has no longer any function, and it is usually more or less degenerated into connective tissue. The *lens* becomes retracted and cataractous—matters of no practical moment, since the eye is already blind. The *iris* and *ciliary body* may remain intact for a great while. I have seen cases showing the signs of ossification which had probably existed for thirty or forty years—where the globe had even assumed a square shape from the traction of the recti muscles—yet no new irritation, no iritis or cyclitis, had been set up in the affected eye or in its fellow. The *outer layer of the choroid* and the *lamina fusca* are, like the iris and ciliary body, often quite unaffected. In these parts run the ciliary nerves, while there are none in the chorio-capillaris or the parts traversed by the transverse septum of bone (or connective tissue). These nerves, therefore, escape irritation, and so the other eye does not suffer, except when we have cyclitis or iritis. Unfortunately these complications are not very rare; indeed, chronic iritis with choroiditis, now called irido-choroiditis, is the disease perhaps most frequently leading to ossification. If the original inflammation is not extinguished, we are apt to get, in some of its exacerbations, pressure on the ciliary nerves, and consequent sympathetic ophthalmia of the other eye, though many attacks may go by without producing it.

The *prognosis* is sufficiently indicated by the considerations just now adduced. There is no hope of preserving, or restoring, the sight of the eye undergoing ossification. There is always a chance of a fresh iritis or cyclitis becoming lighted up in it, and of this producing trouble in the sound eye.

Antiphlogistic *treatment* of the bad eye, for the sake of its fellow, is therefore indicated whenever inflammation occurs. When both eyes are inflamed, both must be treated; and if the sympathetic ophthalmia assumes a grave aspect, prompt extirpation of the ossified and useless eye is the proper measure. It is to be be borne in mind, however, with regard to this last procedure, that it should not be resorted to until the sympathetic inflammation actually appears; for we have seen that, in many cases, ossification may exist for years without the occurrence of any such complication.

CLASSIFICATION OF MEDICINES ACCORDING TO TIME REQUIRED FOR THEIR OPERATION.

BEING REMARKS MADE BEFORE THE NEW YORK ACADEMY OF MEDICINE, DEC. 15, 1870.

BY W. H. THOMSON, M.D.,

PROF. MATERIA MEDICA UNIVERSITY MEDICAL COLLEGE, NEW YORK.

THE great aim in attempting a classification of medicines should be thereby to facilitate their employment. But if this be true, it becomes plain that it is not science in its proper sense which is to be aided by such classification, but art; or, to consider it in a slightly different phase, a true classification of medicines is intended to help, not the memory, but the judgment. I think that this practical purpose should be allowed its due weight at the start, because it has seemed to me that the progress of therapeutics has been hindered by attempts to follow in the classification of remedies the methods adopted in those branches of science whose proper objects of study are the things themselves rather than their uses. The mineralogist, for example, in his classifying, never ranges one sample under the head of building stone, and another as belonging to the precious stones, for human purposes or relations do not come properly within his province. But with a medicine it is not all the article *per se* that claims our interest, as it is that article after it has become an ingredient of the circulation or of the living tissues. Its whole importance, as far as it concerns medical men, consists not so much in what it is as in what it does; or, in other words, it is the action of medicines above everything else about them that should engage our attention, that should direct our investigations, and should mould our classification. In my experience, however, as a teacher of this branch of our art, it has seemed to me that this great practical aim of classification as regards remedial agents has not been carried out in our systematic works on the materia medica as fully as might be wished.

Medicines are first treated with a wearisome fulness of detail about the articles as such, which discourages the student to a degree that is often of itself an obstacle to his acquiring a mastery over them, for he is obliged to spend so much time and effort in learning what the separate articles are, how they are prepared, adulterated, etc., that he has no time to learn what to do with them. This disadvantage, however, might be overcome by application; but there remains the more serious fault which we have alluded to, namely, that the grouping together of the agents is so often after methods, which, while useful enough in wholly different fields, are yet not the best adapted to the great end which a physician has in view.

This fault we would define to consist in regarding the symptoms which follow the administration of medicines

as fit elements for constructing a system of classification. As the entomologist counts the bars on the abdomen, or the spots on the wing of an insect, to determine its place in *his* system, so some of the more striking or patent symptoms which various medicines will produce in common, are accepted as sufficient to bring them together as similar therapeutic agents. Cantharides, for example, is thus wedded to digitalis, because both make urine flow; and in a deservedly esteemed recent work, strychnia follows closely on the carbonate of ammonia as a nervous stimulant. In the same work the student is told that arsenic is a tonic; so is a cold bath, cod-liver oil, and a sea voyage.

Symptomatology is the beginning and the end of the undertaking. A deeper insight than symptoms is not attempted, and little effort is made to discover whether, as in other great departments of science, some one or two master principles may not underlie the whole varied array of phenomena, giving unity to complexity and rewarding the knowledge of them by the gift of skill.

We would therefore beg the indulgence of the Academy for a brief space, while we endeavor to show by a few examples that mere symptoms are just as inadequate towards determining what the real operation or therapeutic uses of a given agent are, as a quick pulse is insufficient to determine the form of a fever, or dyspnœa the nature of a thoracic affection. Symptoms have their place and value in the one case as in the other; but as we cheerfully allow homœopathy to treat symptoms alone, to the utter ignoring of diagnosis, so we must be prepared to apply the same principle in our study of the action of medicines, namely, that as the same symptoms may accompany the operation of very different agents, therefore their significance depends not on themselves, but on their relations, and hence that symptoms can never be by themselves safe materials for laying such a foundation as we need in forming a classification.

Frequent illustrations of the fact that similarity of special symptoms by no means implies any constant similarity of operation, meet us in the investigation of the action of those agents which affect the functions of the glandular system. We choose the case of the glandular system also from the fact that its functions are easier investigated, and seem less complex than some other examples of vital processes, and, moreover, they are characterized by a kind of unity of operation which is often illustrated by the vicarious performance of the duties of a disabled member by one or more of its allies. Now, secretion being the leading glandular function, it seems plainly to follow that we can adopt as the distinguishing feature of the agents which act on the glands, the one symptom of their increasing or decreasing, as the case may be, any particular secretion, and then make our classification accordingly. Thus those agents which increase the renal secretion, for example, are termed diuretics; those which do the same with the intestinal secretions, cathartics; those which check them, astringents, etc. Adopt and inculcate this, however, and the result will be, and actually is, much doubtful practice at the bedside on the part of inexperienced or routine prescribers from what seems a fair inference, namely, that the symptom, *i.e.*, increased secretion or its opposite, is one and the same thing however it occurs. Under the guidance of this notion, opium is classed with tannin, on account of effects on the bowels which are essentially as distinct from the true operation of tannin, as the constipating effect of inflammation of the brain is distinct in its mode from the constipating operation of alum. The true state of the case is that a single symptom is often the only thing which the various agents thus grouped together have in common, all else being diversity, and which diversity should in all logic be taken into account equally with the similarity. Thus opium has just as good a title to be classed among the agents which *increase* gland secretion, as to be called an astringent, for it is actually the surest diaphoretic which we possess. But here again we meet with another form of the uncertainty which results from following the guidance of symptoms, for on tracing their course we will soon find them radiating from the one symptom as a centre, to all points of the circumference as regards their cause or causes. Thus as aids to explain increased secretion, two conceptions are often coupled with the action of the medicines which have this operation, namely, that of direct stimulation of the gland, or else of elimination on the part of the gland. Now, does a Dover's powder directly stimulate the sudoriferous glands after it has paralyzed the intestinal glands; or, on the other hand, is the powder divided up among the millions of the cutaneous tubes, so that each of them bears a share in sweating it out? But admitting both of these as causes of the diaphoresis, what has either of them to do with the universal diaphoresis which breaks out under great fear? Is fear a stimulant to anything, or does fear cause anything to be eliminated?

Let us therefore add another cause of diaphoresis, and say that purely nervous impressions of a depressing character are such; that weakness is a diaphoretic; witness night-sweats, etc.; if so, then how does that purely nervous stimulant, ammonia, cause such prompt sweating? In fact, the one conclusion which such examples force upon us is, that the symptom diaphoresis may have as many distinct causes as the symptom pain; and therefore as no one with the extensive store already accumulated of pathological facts, would now choose the symptom pain—great as it is a symptom—as the basis of classification of *diseases*, neither would *we* speak of a class of diaphoretics, if only we were, as therapeutists, in the same advantageous position as the pathologist.

But analogous instances of doubtful alliances, brought about by symptomatology, meet us frequently in the classification ordinarily followed with the other orders of gland medicines, and examples of which we could instance in detail if time allowed.

The action of gland medicines is simplicity itself compared with the operation of those agents which influence the functions of the nervous system. Instead, therefore, of being a great unit, as common language would seem to imply, its infinity of special functions dependent upon their corresponding centres or nerves, makes it an absurdity to speak of any medicine as acting on the nervous system as such, for that is never what the nervous system does itself, to act, or to be acted upon as a whole. What even the most powerful narcotics affect is only one or two, or at most a very few, out of the vast number of special nerve-centres which compose this system, but never all of them, or any considerable number of them. By one nerve, for example, we see, or taste, or hear; by another we feel pain; by another we do not feel at all; it is a nerve of motion, or a spinal or vaso-motor, or inhibitory nerve, or nerve-centre, etc., etc. So that it would be even more possible to conceive of every flexor, extensor, voluntary, and involuntary muscle of the body starting into simultaneous activity, than to imagine such a wonderful thing as a general nervous stimulant, or general sedative, unless in the latter case it be death. To characterize any agent, therefore, as a nervous stimulant, or nervous anything, is to use language so vague as to come very near having no meaning at all.

We must, therefore, choose, as our first task, the localization, if possible, of the operation of a given narcotic, and not till this be done attempt to define the nature of that operation. It is something to be able to do even this, to determine what part of the nervous system is acted upon. Thus it is well to find that digitalis acts on the nerves of the heart, but whether that action is indicative of a strong sedative, or just the reverse, to an overpowering, stimulant impression on those nerves, is still a matter of doubt. There are two ways at least, if not more, of making the heart beat as digitalis does, so that while some authorities term it a cardiac paralysis, others praise it as a powerful cardiac tonic. Here, therefore, as with glandular medicines, the symptom is not the complete exponent of its cause; in fact it is much less likely to be so than in that case, for we have here no such tangible objective element as a secretion which can be inspected, tasted, or analyzed, but the manifestations of function only, and that function the most intricate and complex of all the workings of life. Reliance on the symptoms, therefore, of narcotics affords us anything but a satisfactory basis for classification. In the administration of no other order of agents do we meet with so many individual idiosyncrasies, that is, of very diverse symptoms being produced by the same agent in different individuals. To one patient we give a dose of opium, for example, to procure sleep, and the result is gratifying; but the identical dose given to another for the identical indications of the first, is followed by anything but sleep, he becoming crazed by a wakeful activity of the imagination that borders upon maniacal delirium. What other inference can we draw from this than that symptoms here are but superficial indications, which are dependent on secondary causes, and hence that their guidance can lead us but a little way to the deeper and real relations in the operation of these agents?

The speaker alluded to tonics, and to the class of specific remedies like arsenic, iodine, and bichloride of mercury, and their effects, showing that these agents are not symptom remedies. They do their work well, but health alone is their symptom.

In considering the analogous relations of symptoms in the field of pathology, we should first take note of the present inferior status as regards the opportunities for eliciting symptoms on the part of the therapeutist compared with the pathologist. It is safe to say, that when a pathologist examines a case of disease, he has ten symptoms of the operation of disease to one which the therapeutist has of the operation of medicine. The posture of the patient, the expression of the countenance, the tone of the voice, the complaints of the sufferer himself, then the *tactus eruditus*, and lastly the skilled ear of the investigator, all help to swell the quota of the signs which as premises are to lead to the inference. But this by no means sums up all the advantages which he possesses. Let all these fail of affording certainty, there yet remains that great centre of interest, the post-mortem table. Indeed, we have more than one learned acquaintance who sometimes appear to regard a fellow-being's chief reason of existence to consist in his developing something that could be presented at the Pathological Society, and who are ready to discard, as grounds for determining the true nature of a case of disease, all the other signs put together compared with those which are afforded by an examination of the dead body. In the late discussion in the Academy, for example, on the nature of pulmonary phthisis, clinical experience, or anything else that could not show cause to the scalpel or microscope, seemed to some, if we interpret them fairly, as having no show whatever.

. . . . . .

Quite parallel to the bearing of time distinctions between acute and chronic diseases, do we find the distinctions between short-time and long-time medicines. The field for the employment of short-time remedies is almost exclusively in the management of acute diseases, while the long-time medicines are remedies only for chronic diseases. Ammonia, for example, a transient neurotic, is of little use against the panting debility of chlorosis; iron is of as little use against the trembling debility of typhoid fever. If we look a little farther, we find why this is so. Short-time medicines are almost entirely symptom medicines; that is, their operation is simply that of producing certain symptoms in the system, and nothing else. Hence their action is just the same, whether they are operating on a healthy or an unhealthy system. Tartar emetic, for instance, will prostrate or vomit any person in the best of health; opium, in its appropriate dose, will benumb whoever takes it; and a cathartic is always a cathartic. What, therefore, we employ them for, is to produce by them symptoms which will neutralize an opposite class of morbid symptoms, but not to do more than that, for we do not expect by them to cure the diseases themselves.

. . . . . .

The theory, which for so long held disastrous sway over the profession, that a fever, or any other acute disease, could be eliminated by purging, sweating, or even bleeding, is now pretty generally abandoned for the truer view, that all that glandular medicines effect is, to remedy the complications which we have referred to. For acute diseases cannot be eliminated; we must let them run their course, which, from their original nature, is a fixed course, with the tendency to recovery. Our business as physicians, therefore, is to mitigate symptoms, as they arise, by symptom remedies, and to ward off complications, biding our time meanwhile for the few days, or even hours, which are allotted to the acute affection.

But with the long-time medicines all is different. In the first place, their remedial operation is not accompanied by symptoms. We do not mean to say that they cannot, or do not, produce symptoms, for some of them do; but it is instructive to note, that *if* they do so, then they are not acting in the way which was intended. Thus mercury is often used as a cathartic, that is, as a symptom remedy; but when so, then it fails of operating as a constitutional remedy, so that it has long been inculcated, that if you aim at obtaining its alterative effect, you must give it slowly, in small and repeated doses, and prevent it from going off by the bowels. Iron will occasion headache, and iodine symptoms peculiar to itself; but if so, then they are not acting properly. Moreover, the other contrast with symptom remedies is equally striking and significant. The action of symptom remedies being merely to cause symptoms, it matters not whether the system is in a state of health or in a state of disease, they will act all the same, subject, of course, to individual or unessential modifications. But long-time remedies are not to act against temporary symptoms, but against the diseases themselves, or in long standing morbid states. Hence they do not act the same on the healthy as on the sick. Iron and cod-liver oil are no assistance to a person when he is not a patient, they cannot make him a whit stronger than does his daily food, if of good quality. So mercury benefits him only who has come to need it from syphilis or from a few other causes; and a man must be really ill before he can thrive on arsenic. What we accomplish, therefore, with this class of agents, is to pass far beyond symptoms, or even beyond short-time diseases.

We act upon the processes of life and nutrition themselves, to deal with perversions of a profounder nature than catarrhs or colds, or, in a word, anything that can be "caught," from a common sore throat to small-pox. Settle it, therefore, that the particular complaint is not an acute or short-time malady, and your class of remedial agents for dealing with it is also determined. Symptom remedies, with their very limited and very transient operation, will in such instances do little else than palliate a few symptoms of the disease, and even this they will do but imperfectly if the symptoms have their origin in serious constitutional causes. As a rule, symptom remedies are scarcely more than makeshifts, adapted for temporary exigencies. The other class, on the other hand, are the true remedies, whose right use enables the physician to cure what nature herself cannot cure. If they act at all, their operation has for its seat a field which is far removed from the action of neurotics, or of glandular medicines, or of anything which can do its whole work in a few minutes, for they affect the processes which govern either the make of the living cell itself, or the forming conditions necessary to its function.

If time would allow, we would have desired to show that the essentially remedial operation of the class termed alteratives, so closely resembles the operation of the class usually termed tonics, that we may regard them as the same in kind, only that alteratives are very limited, or, as we might say, specific in their operation, while their tonic allies have wider applications. It may seem strange to connect mercury and iron together as like remedies; but at least we will say that so closely are they allied, when mercury is really remedial, that it greatly promotes the action of mercury against syphilis to have it aided simultaneously by iron, cod-liver oil, and quinine, and similar constitutional sustainers. Often do we find that mercury or the iodide of potassium will not benefit, but do harm, unless we first secure the influence of the other division of time remedies. So also arsenic will frequently not cure but aggravate a leper, unless we first build up, as practical men have expressed it, the patient's system. But we cannot now enter upon either the distinctions between the short-time remedies among themselves, or the long-time among themselves, as our subject is more properly the demonstration of the value of the element time in the operation of an agent, as an indication of its true status when regarded from a therapeutic point of view. For, as we remarked in the beginning of our essay, practical applications should be the determining influences in the construction of systems of classifications when remedies are the subject of investigation. What special advantages, therefore, result to the physician when pondering how to deal with a disease by this time principle of distinction between remedies? Let us take for illustration the single class of nervous diseases. Neurotics are the medicines whose operation is specially that of affecting or modifying the functions of the nervous system, of producing nervous symptoms in short.

But neurotics are short time, mere symptom medicines, soon acting and soon passing. What is the practical inference, therefore, other than that notwithstanding their seeming close connection with the nervous system, they are almost useless in the treatment of real nervous diseases? True nervous diseases are characterized by the most potent and remarkable of all morbid symptoms, only that they are intermittent. Hence, because they manifest themselves generally at intervals, the symptoms are frequently mistaken for the disease itself. A paroxysm of asthma, for example, is taken for the disease asthma, and the neurotics, stramonium or belladonna, are spoken of as remedies for asthma. They are no such thing, just because they are neurotics, and therefore can relieve nothing but symptoms; no one is ever cured by them of asthma, but only of the asthmatic *paroxysm*.

If you wish to cure asthma, try such slow-acting agents as arsenic, or iodide of potassium, or nitrate of silver, or a seton in the nape of the neck, which cannot act against the paroxysm, or in other words, the symptom, when it occurs; but if faithfully pursued will often remove the disease itself, of which the bronchial spasm is but one of its manifestations.

Epilepsy seems to be one of the most typical examples of a nervous disease. It does not affect the temperature of the blood, nor derange the constituents of a single secretion, or apparently do anything except cause purely nervous disturbance. But epilepsy is anything but a mere nervous complaint; its history may be traced till it passes without doubt from its origin into the deepest recesses of nutrition; so that it is not a sensational expression to say, that in some cases epilepsy began at the first moment of conception, like what the alienist rightly maintains as true of certain cases of insanity.

Now, after a considerable experience in the treatment of this disease, I would say decidedly that neurotics are as useless against epilepsy as opium is against phthisis. I would rather, if left with but two remedies against this complaint, select cod-liver oil and the hypophosphites, than I would the whole class several times over of the so-called antispasmodic nervines.

Neuralgia certainly is a nervous symptom, but it also—and in fact generally—is a disease; and when that is the case every neurotic should be abandoned, unless for the momentary effect of benumbing an uncontrollable paroxysm, when we might have recourse to chloroform, simply to sleep through the attack, but certainly not to remove the neuralgia, for the malady itself, if cured at all, can be cured only by slow modifiers of the constitutional condition.

These examples probably may suffice to illustrate our position. If we are correct in assigning to the element Time so much practical importance in the determination of the nature of remedial agents, we may hope that the undertaking is of some practical use. Classified simply according to their symptoms, or supposed symptoms, remedies seem to us like a great ill-disciplined army, which, the more numerous it is, the more difficult is it to handle, and which, when brought up in such fashion against the enemy, soon turns into a confused mob, in which leaders and led become hopelessly mixed together. Classified, however, according to the more comprehensive and practical element of Time, each division then takes naturally to its own work, each arm of the service is known, so that light cavalry are never expected or commanded to do the work of heavy infantry, or, in other words, mere symptom remedies will not be pitted against such enemies as serious constitutional diseases.

SKIN-GRAFTING.—J. J. Chisolm, M.D., Prof. in the University of Maryland (*Richmond and Louisville Med. Journ.*), alludes to his three successful operations of transplanting epidermis into the raw surface of old ulcers, for the purpose of promoting their healing. This surgeon states that the operation, first introduced recently by Reverdin, of Paris, and repeated by Dr. Geo. Pollock, of St. George's Hospital, London, and others in this country, is particularly adapted to chronic ulcers, more especially those resulting from extensive burns, which heal to a certain extent, but cannot be urged to a final closing.

A CASE OF PLASTIC OPERATION

PERFORMED FOR THE

CLOSURE OF AN OPENING IN THE RIGHT SUPERIOR NASAL FOSSA.

By GURDON BUCK, M.D.,

SURGEON TO NEW YORK HOSPITAL AND ST. LUKE'S HOSPITAL.

Margaret Kelley, æt. 21, native of Ireland, unmarried, admitted into New York Hospital, March 3d, 1869. Patient, now in the enjoyment of good health, states that about nine years ago, after scarlet fever, a dark spot appeared on the upper part of the nose, on the right side, and occasioned the opening which still exists. Its situation and shape are accurately represented in the accompanying figure, taken from a photograph. It is of an elongated ovoid form, one inch and a half in its vertical diameter, and three-quarters of an inch in its longest transverse diameter. It opens largely into the right nasal fossa, its outer margin approaches close to the inner canthus of the right eye. The skin at the margin is everywhere supple, and dips somewhat into the cavity. The interior surface, as far as it is visible, is healthy in appearance. The voice is unaffected. The disfigurement occasioned by the opening being very conspicuous, patient is naturally anxious to have it, if possible, removed. She keeps it constantly covered by a patch of adhesive plaster.

Operation, March 5th, under ether.

The skin at the margin of the opening was everywhere detached and everted, a process requiring extreme care, owing to the thinness of the skin, especially at the inner canthus of the eye. An exact pattern of the shape of the opening was then cut from oiled silk, and served to shape the patch of skin intended to be raised from the forehead for closing the opening. The pattern was laid upon the forehead, so that the patch of skin to be raised should retain its connection above and corresponding to the left supraorbitar notch, where it would derive its support directly from the branch of the ophthalmic artery emerging from the orbit. The pattern was laid on, not vertically, but obliquely, so that its long axis inclined to the right side at an angle of about forty-five degrees with a horizontal line. An incision was now carried through the entire thickness of the skin around the edge of the pattern, and the included patch of skin dissected up from the pericranium, except below where it was to retain its connection. The dark line, *c*, *a*, *b*, Fig. 1, marks the boundary of the patch. A narrow strip of skin, covered partly by the eyebrow, intervening between the patch just raised and the upper and inner margin of the opening, was divided across at its lower end, *c*, *d*, and dissected up to make room for the patch. The patch was next brought round edgewise from left to right, and applied over the opening, thus making a circuit of a little more than a quarter of a circle. It was secured in its new place by two pin sutures inserted at opposite points near its base, and one at its extremity; these were wound with figure of eight turns of cotton yarn, and between them fine thread sutures were inserted close to each other. The narrow bridge of skin raised to allow the patch to be brought into place, was transferred to the bare surface upon the forehead from which the patch had been dissected up, and was found sufficient to fill it up, so that no bare surface was left uncovered. Fine sutures were employed to complete this adjustment and terminate the operation. Tepid water dressings were directed to be kept applied to the parts. The subsequent progress was favorable. Primary union took place throughout the whole circuit of the transferred

Fig. 1.

Fig. 2.

patch, except about one-fifth of its circumference, which bordered on the inner canthus of the eye, where union failed in consequence of the opposite edges of the wound becoming inverted. To remedy this defect, a second operation was performed April 6th. The ununited edges were pared afresh, and two pin sutures inserted with special care to evert the edges and hold their cut surfaces incontact. Additional fine thread sutures were also necessary to complete the adjustment. A perfectly successful result followed this operation. The transplanted patch in its new situation formed a rather conspicuous

bulging ridge, particularly across the upper part of the nose, where the twist had taken place. To remedy this disfigurement, a third operation was performed on the 17th April. A prism-shaped slice of skin was excised from the summit of the ridge along its entire length, and the edges accurately brought into coaptation and secured with fine thread sutures inserted close together. This operation did well, and accomplished what was intended, the levelling of the surface, and a great improvement of the appearance of the face. On the 4th May, patient was discharged, much gratified with her improved condition. (See Fig. 2.)

NEW YORK, No. 46 West 29th street.

Reports of Hospitals.

MANHATTAN EYE AND EAR HOSPITAL.

A CASE OF ACUTE INFLAMMATION OF THE EXTERNAL AUDITORY CANAL, CAUSED BY IMPACTED WAX.

REPORTED BY D. WEBSTER, M.D.,
HOUSE-SURGEON TO THE HOSPITAL.

D. H., aged 28, laborer, presented himself at Dr. Roosa's clinic, at this hospital, Nov. 1st, 1870. Five days previously his right ear was attacked with pain, tinnitus, and deafness, which symptoms had gradually increased up to date. He had slept but little for the last two nights, in consequence of the severity of the pain. He could hear the ticking of an ordinary watch at the distance of only one inch.

Upon examination we observed a little puffiness of mastoid process, some swelling back of the angle of the lower jaw and of the walls of the meatus. There was also some pharyngitis. Through the aural speculum the external meatus was seen to be plugged with hard wax. This was removed by carefully syringing the ear with warm water. Some pus was found in the canal, and at first the membrana tympani was thought to be perforated, but upon more careful examination it was found to be intact, though a complete examination of it was rendered impossible by the narrowing of the meatus consequent upon the swelling.

Politzer's method for inflating the middle-ear was practised, and the patient was directed to fill his ear frequently with warm water.

Nov. 2. He said that the pain was so relieved, that he rested well last night, and complained more of a sensation of soreness than of pain. The tinnitus and swelling were undiminished, but the hearing distance had risen to ten inches. On using Politzer's method, the patient felt the air enter neither ear, and when this was done again with the addition of the vapor of chloroform, as first practised by Dr. J. S. Prout, it was felt only in the left. He was directed to continue the use of warm water.

Nov. 3. The swollen walls of the meatus had become more sensitive to the touch, and the pain had returned. He was treated with the warm aural douche, Politzer's method again used, and the entrance to the meatus stuffed with cotton in order to exclude the cold air.

Nov. 5. The swelling had increased. Dr. Prout, who saw the patient for Dr. Roosa, made two incisions in the walls of the meatus—one backwards, the other upwards. Pus followed the knife in the latter. The pain caused by the incisions was immediately relieved by the warm douche (Clarke's aural douche).

Nov. 8. He was again seen by Dr. Roosa. There was an abscess in the anterior wall of the meatus, just behind the tragus. This was opened, and a considerable quantity of thick pus evacuated. The meatus was as thoroughly as possible cleansed by syringing, and the use of pledgets of cotton.

Nov. 15. The swelling had so far diminished that the drum-head could be properly examined. It was covered with bits of wax and epidermis, which were removed by gentle syringing. The hearing distance was twelve inches. A week later Dr. Roosa pronounced the patient cured so far as the ear was concerned, all signs of irritation having disappeared, no tinnitus remaining, and the hearing function being restored to its normal condition. A gargle of alum and chlorate of potassa was used for his pharyngeal trouble.

A point of especial interest in this case is its causation. As the membrana tympani remained intact throughout, as even after the swelling had subsided small particles of wax still adhered tenaciously to the surface of the drum-head and of the walls of the meatus, and as no other cause could be assigned for the inflammation, we could not avoid the conclusion that it was due to the impacted cerumen acting as a foreign body.

Similar cases are very rare. Tröltsch does not mention impacted wax as one of the causes of otitis externa, though he says that sometimes it sets up irritation in the walls of the canal and the outer surface of the membrana tympani, and the translator informs us, parenthetically, of a case in which it caused "acute inflammation and perforation of the drum" (page 83, 2d edition).

This is the only case of the kind that has occurred in this hospital during the two and a half years of its existence, during which time about eleven hundred and fifty ear cases have been treated.

Reviews and Notices of Books.

FIRST MEDICAL AND SURGICAL REPORT OF THE BOSTON CITY HOSPITAL. Edited by J. NELSON BORLAND, Physician; DAVID W. CHEEVER, Surgeon. Boston: Little, Brown & Co. 1870. 8vo., pp. 684.

ON the completion of the fifth year of the establishment of the Boston City Hospital, the trustees desired the medical staff to prepare an enlarged consolidated report. The duty of editing it was intrusted to a committee consisting of Drs. Borland and Cheever. All the departments have been represented, and general, medical, and surgical statistical tables have been added. The articles contained in this well-printed and bulky volume—made unnecessarily thick and unhandy from the heavy quality of the paper used—will compare favorably with those of the Hospital Reports published either at home or abroad. Some of them are of great value. The editors have been judicious in their selection, and the chief contributors have done their work well. The first article is on perinephritic abscess, by Dr. Henry J. Bowditch. Dr. David W. Cheever contributes Articles II., IV., VIII., XI., and XIII., respectively on excisions of joints, on displacement of the upper jaw, on reproduction of the tibia, on encephaloid tumor of tonsil, occlusion of the vagina, and a surgical abstract. Article III., cases of pneumonia, is by Dr. J. Nelson Borland. Article V., treatment of acute rheumatism, is contributed by Dr. John G. Blake. Article IV., by Dr. Howard F. Damon, is on the treatment of skin diseases. A very valuable paper on typhoid and typhus fever, by Dr. J. Baxter Upham, is Article VII. The two following articles are, an

ophthalmic report by Dr. Henry W. Williams, and an aural report by Dr. J. Orne Green. In Article XII., the subject of periuterine inflammation is well treated by Dr. Alexander D. Sinclair. If the subsequent volumes of these reports maintain the reputation which the present one is sure to have, we may expect a valuable annual contribution to medical and surgical practical literature, and shall await them with pleasure.

On Diseases of the Spine and of the Nerves. By Charles Bland Radcliffe, M.D.; John Netten Radcliffe; J. Warburton Begbie, M.D.; Francis Edmund Anstie, M.D.; and John Russell Reynolds, M.D. Philadelphia: Henry C. Lea. 1871. 8vo., pp. 196.

For the composition of this imposing, but incorrect, title-page the publisher and not the authors are responsible. The book is a reprint of some of the articles in the second volume of Dr. Russell Reynolds's "System of Medicine," published more than two years ago, a second edition of which is now passing through the press in London, and will be shortly issued. It has already been printed in the *Medical News and Library*, during the past year. The articles are of unequal value, and the statement in the "Publisher's Note," that "the volume will be found to present the latest advances in the knowledge of the several subjects therein discussed," is business-like, both in spirit and phraseology, but entirely gratuitous and inexact. The most important contributions to the disorders of the spinal cord—with which this book is chiefly concerned, and not the spine, as its title misleadingly states—have been made since these articles were written, and there is consequently no note of them. On the other hand, there is an excellent paper on epidemic cerebro-spinal meningitis—entirely out of place in a work on diseases of the nervous system, and which in the new English edition has been transferred to the first volume on General Diseases—by Mr. J. Netten Radcliffe; and another equally good on neuralgia by Dr. Francis Anstie.

Materia Medica for the Use of Students. By John J. Biddle, M.D., Professor of Materia Medica and General Therapeutics in the Jefferson Medical College, etc. etc. Fourth Edition, Revised and Enlarged, with Illustrations. Philadelphia: Lindsay & Blakiston. 1871. 8vo., pp. 381.

Professor Biddle tells us in his preface that the present edition of this popular work has been carefully revised and much new matter added. Most of the articles have been modified, some rewritten, and many new ones added. Recent additions to the materia medica have been introduced, and the defects and shortcomings of previous editions have been to a degree rectified. The present is certainly an improvement on former issues of this work. The illustrations, to our mind, do not add to its value; they increase its size, and take up room which might be used more profitably to the reader. The diagrams of the instruments employed in the atomization of liquids do not represent those most generally used by those who do much with this means of topical indication. The dose of bromide of potassium is stated at five, ten, and *even twenty* grains. Little can be done with less than twenty grains, and thirty grains to a drachm is the dose most commonly required. Nothing is said about the effects so frequent from its persistent employment, and it is asserted "to be the most efficient remedy which we possess in allaying venereal excitement," a statement which those who have often tried it under these circumstances would, we suspect, decidedly demur to. The dose of phosphide or phosphuret of zinc is given as $\frac{1}{16}$th of a grain; whereas one-tenth of a grain is the ordinary dose.

The style of the volume is attractive.

Chemistry, Theoretical and Inorganic. By Geo. F. Barker, M.D., Professor in Yale College. C. C. Chatfield & Co., New Haven, Conn. 12mo., pp. 275. 1871.

Chemistry is something that concerns every member of the human family, and especially physicians, who ought to be, if they are not, well familiar with the state of chemical science, and with all its leading and many of its special departments.

Prof. Barker is at that time of life when scientific men do their best work, and he has succeeded in producing a treatise which for thorough representation of modern rather than ancient ideas, for compactness of style and arrangement, and for clearness and accuracy of definition, is, we think, unsurpassed. Few tasks so rack and worry and weary, even the best disciplined brain, as preparing precise and lucid definitions to the terms of a growing science. This task Prof. Barker has performed with great painstaking and signal success.

The only fault we have to find with the work is, that it is too small, at least for the very large number who cannot attend chemical lectures, or for the still larger number who are obliged to attend very poor lectures.

It is unfortunate that chemical lectures for medical students do not more fully represent the progress of modern science, so that physicians should not be obliged to depend on their own exertions for their chemical knowledge.

This book is an unsurpassed guide for those who attend lectures where the system on which it is based is taught, and well taught; but there is much needed a work for those who are obliged to depend on text-books—a work which shall contain all that this work contains, and much more; which shall be made interesting as well as true, and practical as well as theoretical; which shall state facts as well as principles, and give anecdotes, it may be, as well as definitions; that, in short, by its fascinations as well as by its thoroughness, shall commend the noble science of chemistry to those who suppose that they have no love for it, and be, so far as possible, at once a teacher, a lecturer, and a text-book for the hosts of wandering sheep who have no shepherd. Such a book, we hope that Prof. Barker will in time prepare, and that, too, before he has lived long enough to grow into enervation. The typography of the book, we may add, is perfect and peerless, and greatly adds to its value.

Progress of Medical Science.

Formation of Urea in the Liver.—Dr. Cyon of St. Petersburg has published in the *Centralblatt für Medizin. Wissenschaft* an account of some researches made by him, from which he infers that urea is formed in the liver. Blood withdrawn from the carotid arteries of dogs was rapidly defibrinated; part of it was placed in an apparatus arranged for propelling it through the liver by mechanical pressure. Three canulæ were introduced, one into the inferior vena cava, a second into the hepatic vein, and a third into the portal vein. The first of these was connected with an aspirator consisting of two cylinders partly filled with mercury; the other two were connected with the vessels containing blood. The blood was now allowed to flow through the liver; and, after it had flowed through the organ several times, the quantity of urea was deter-

mined by Liebig's method, and compared with that in the ordinary blood of the animal. The blood which had passed through the liver was found to contain the larger quantity of urea. In 100 cubic centimetres of blood sent twice through the liver of a moderate-sized dog, there was 0·14 gramme of urea; in the same quantity of blood not so treated, the amount was 0·09 gramme. When the blood was sent through the liver four times, the amount of urea in 100 cubic centimetres was 0·176 gramme; that in a similar quantity of the ordinary blood of the animal being 0·08 gramme.—*Wiener Medizin. Wochenschr.*, Oct. 29, 1870.

EXPERIMENTS BY BROWN-SÉQUARD.—Dr. Brown-Séquard publishes a paper in the *Lancet* of 6th ult., calling attention to his recent experiments on the effects of injuries of the brain on the lungs. He finds injuries to the base of the brain followed by hemorrhage, œdema, emphysema, etc., of the lungs. He says:—"When I publish the details of my experiments on the influence of injuries to the brain on the lungs, I will show that, in man, diseases of or injuries to the brain very frequently produce organic alterations in the lungs. I will content myself here, to prove the frequency of that morbid influence of the brain on the pulmonary organs, to state that, out of 188 cases of organic disease of the brain recorded by Calmeil, there was a morbid state of the lungs, especially inflammation, in more than 60 cases—*i. e.*, in one case out of three. I have no doubt that many patients attacked with brain diseases die from a disease of the lungs caused by that of the central organ of the nervous system."

SYPHILIS IN THE FEMALE.—Mr. Evans, an army surgeon who wrote a most excellent work on venereal sores, remarks that "an altered secretion that cannot be detected is sufficient for the production of disease," adding that, when he attended the examinations of 200 women of the lowest description, who were frequented by the soldiers belonging to the army of occupation at Valenciennes, no disease could be detected in the women, and yet the hospitals were filled by diseased soldiers infected by these very women. He noticed exactly the same thing at Lille, and observes that "the condition that communicates disease in the female is only to be known by its effects."

Dr. Macloughlin, who was for twenty-seven years in practice in Paris, whenever a gentleman applied to him suffering from syphilis, endeavored to ascertain from what person the disease had been contracted; and it was his regular practice, in company with the French police-agents, to visit the brothels and find out the person who had communicated the disease. He took considerable trouble in this matter, and used on each occasion to give the police-agent and the woman each a Napoleon. In all these cases the woman was submitted to careful examination by the police-surgeon, himself, and others; and Dr. Macloughlin declares that "it was excessively rare for them to discover the source of infection in the female." In one gentleman, where secondary symptoms of a severe type were developed very speedily after the primary symptoms—a case pronounced to be unequivocal syphilis by M. Biet and others—the only two women with whom the patient had ever had connection were brought up and repeatedly examined by five or six medical men, including the police-surgeon, and not the slightest trace of disease could be detected in either of them. Dr. Macloughlin had unusual opportunities for studying the disease in Paris and elsewhere; and, whatever we may think of his peculiar opinions, no one can deny that his testimony as to facts is thoroughly trustworthy.

Mr. Skey, in a letter written to Dr. Macloughlin in May, 1864, and referring to these facts, says that he is convinced, in common with many surgeons, that discernible disease in the female is not necessary to the production of venereal disease in the other sex; and that every variety of sore, and every form of purulent discharge, from the slightest to the most intense, can be contracted from women who have not in their own persons indications of disease of any kind.

Dr. Aitken says, in his work on the Science of Medicine, fifth edition: "Medical inspections are formal, and look useful, but the infecting sore, the true syphilitic one, can rarely be detected in the female." In another part of his work he observes: "The syphilitic sore, when it does occur in women, is readily overlooked, even when searched for with great care, aided by a vaginal examination with the speculum."

M. Simon, who is acknowledged to be one of the first pathologists in Europe, says: "The various local states which most habitually spread the infection of true syphilis are constantly overlooked in examinations made expressly for their discovery."

Dr. Alfred Fournié, who has succeeded M. Ricord in the Hôpital du Midi, the venereal hospital for males in Paris, has written a thesis on syphilitic contagion. In conjunction with M. Puche, he carefully traced the disease to its source in 873 cases. Out of the 873 cases coming promiscuously under the care of these gentlemen, 625 contracted syphilis from women registered by the police, and carefully and frequently examined by the police-surgeon.

Dr. Vintras, in his evidence before the Venereal Commission, says, in confirmation of the above facts: "You will find that almost all chancres—the local sores that produce true syphilis—are, in Paris, derived from women who make prostitution their sole business," and are consequently registered and subject to periodical examinations.

So well is the contagious nature of apparently healthy secretions of persons who have suffered from secondary syphilis understood on the continent, that Guichard and Davila insist that not only must the genital organs be carefully introspected, but also the anus, mouth, throat, stripped skin, etc.; and Lanceraux, in his recent work, remarks: "Since it has been admitted that secondary lesions are contagious, and that they produce infection more frequently perhaps than the primary lesions, introspection of the anus becomes indispensable."

In a recent lecture published in the *Lancet*, Mr. Skey stated that some of the worst cases of gonorrhœa were derived from women free from disease, but who had recently recovered from menstruation.

The practical inference to be derived from the above is simply this—that no method of examination can guarantee freedom from disease, either syphilis or gonorrhœa.

Mr. Morgan, speaking of the duality of venereal sores, says that, in women,

"1. The ragged, soft, pus-secreting sore at the fourchette or nymphæ, is the most frequent; but constitutional signs are also almost invariable.

"2. Suppurating bubo is comparatively rare.

"3. Induration of the glands is by no means so marked as in the male.

"4. Infection seems frequently to originate in a vaginal discharge (possibly a true gonorrhœa); this is followed by mucous patches; and these herald in constitutional evidences, the occurrence of a sore being often not discoverable.

"5. Just as with the male, texture seems to influence the induration; a sore on the nymphæ may be hard, and

of an inflammatory type, but true induration is found most frequently on the labium."—*Med. Times & Gazette.*

Fungoid Growths in Choleraic Discharges.—Assistant Surgeon Lewis, M.B., of England, having been sent to India to investigate into the truth or otherwise of the hypothesis put forward by Professor Hallier, of Jena, and others, as to the fungoid origin of cholera, sums up his results as follows:—That no "cysts" exist in choleraic discharges which are not found under other conditions. That the cysts or "sporangia" of fungi are but very rarely found under any circumstances in alvine discharges. That no special fungus has been developed in cholera-stools, the fungus described by Hallier being certainly not confined to such stools. That the still and active conditions of the observed animalcula are not peculiar to this disease, but may be developed in nitrogenous material, even outside the body. That the flakes and corpuscles in rice-water stools do not consist of epithelium, nor of its *débris;* but that their formation appears to depend upon the effusion of blood-plasma, and that the "peculiar bodies" of Parkes, found therewith, correspond very closely in their microscopic and chemical characters, as well as in their manifestations of vitality, to the corpuscles which are known to form in such fluids. These are generally, to a greater or less degree, associated with blood-cells, even when the presence of such is not suspected, especially as the disease tends towards a fatal termination, when the latter have frequently been seen to replace the former altogether. Finally, that no sufficient evidence exists for considering that vibriones and such like organisms prevail to a greater extent in the discharges from persons affected with cholera, than in the discharges of other persons, diseased or healthy; but Mr. Lewis is unable to prove or to disprove whether the vibriones, bacteria, and monads (micrococci) are peculiar in their nature, or whether they are able to give origin to peculiar phenomena in a predisposed person.—*The Lancet.*

The Local Treatment of Cancer was the subject of the second question discussed before the recent Medical Congress at Florence. In addition to removal by surgical interference, which was sustained by the majority of surgeons as the only efficacious means of cure, attention was called to two papers, the first from Dr. Neftel of this city, upon the effects of electrolysis; the second from Professor Schiff, upon the action of pancreatic and of gastric juice. This physiologist had experimented upon two fragments of the same cancer with these juices, and attributes a greater value to the former, which, according to his investigations, digests the tumor without attacking the blood-vessels and exposing the patient to hemorrhage. The gastric juice destroyed *all* the tissues, while the pancreatic juice attacked only the cancer-cells.

Saponified Cod-Liver Oil.—Dr. Van den Corput, Prof. of Clinical Medicine at the St. Jean Hospital, Brussels, has lately published a paper on the advantages he has derived from the employment of cod-liver oil saponified by him in the treatment of tuberculosis, particularly in its early stages. His formula for this soap is as follows: 100 grammes of cod-liver oil are to be saponified by means of hydrated lime, and then aromatized by 1 gramme of essence of bitter almonds, or anise. This mass is to be divided into boluses of 25 or 30 centigrammes, which may be rolled in a mixture of sugar and iris powder, and covered, if required, with etherial tincture of tolu. From 6 to 10 of these are to be taken daily, two at a time, immediately after a meal. In certain cases, other substances that are indicated may be associated with the soap.

The direct advantages of the preparation as a medicinal agent are: its solid form, and its slight and not disagreeable taste. In consequence of its easier ingestion and assimilation, it does not disturb digestion, and does not give rise to the diarrhœa so often caused by the cod-liver oil alone.

The preparation is contra-indicated when in very advanced phthisis there is excessive hectic, and the digestive organs have undergone serious alterations. It should also be suspended when hæmoptysis exists; still, even in the third period of the disease, it produces in many cases a very marked sedation of most of the hectic symptoms. Usually, diarrhœa ceases or diminishes; the evening exacerbation of temperature declines; the colliquative sweats diminish, and the weight of the body sensibly increases. Sometimes, even, the remedy has seemed after prolonged employment to have led to the cicatrization or drying up cavities of moderate size.—*Med. Times & Gazette.*

The Virtue of the Sunflower.—Mr. Martin, in a paper presented by him to the *Société Therapeutique de France*, affirms that the common sunflower, extensively cultivated, has the effect of neutralizing the unwholesome vapors which are so fatal to health and life in marshy districts. The Dutch, who live only by dyking and draining their low lands, and are therefore good authority, pronounce sunflower culture a specific for intermittent fever, the scourge of Holland. They assert that it has disappeared from every district where the experiment has been tried. It is not yet known whether this is the result of its rapid growth producing oxygen, or whether it emits ozone and destroys those germs, animal and vegetable, which produce that miasma which brings fever in its train.

A Case of Favus.—Dr. Pick reports in the *Archiv für Dermatologie und Syphilis* a case of favus, where the only place where the crust was present was on the glans and sulcus coronalis of the penis. On the inner surface of the left thigh, where there was a contact of the scrotum and thigh, there was a ringed herpetic eruption of a parasitic nature. A careful examination of the glans and sulcus coronalis was made, and no trace of hair-follicles was discovered—a point of interest, as it is insisted by Bazin and others that the presence of hair-follicles is necessary to the development of favus.

Galileo's Sphygmonome.—In the interesting life of Galileo, lately published by Macmillan & Co., occurs the following paragraph respecting the sphygmograph:—

"The connection of the great bronze lamp in the nave of the cathedral at Pisa with Galileo's earliest mechanical discovery, is well known. Viviani says that, having observed the unerring regularity of the oscillations of this lamp and of other swinging bodies, the idea occurred to him that an instrument might be constructed on this principle which should mark with accuracy the *rate* and *variation* of the pulse. Such an instrument he constructed after a long series of careful experiments. This invention, though imperfect, was hailed with wonder and delight by the physicians of the day, and was soon taken into general use under the name of the *pulsilogia*."—*The Lancet.*

Laminaria Tents.—Dr. J. C. Nott, of New York (*Am. Jour. of Obstetrics*), presents the following conclusions in regard to the use of laminaria tents:

1st. Where moderate dilatation is required, the laminaria is preferable to the sponge tents.

2d. If placed in warm water, just before introduction, for a few minutes, they become flexible, coated

with mucilage, are easily curved to suit the cervical canal, and may be inserted with the utmost facility.

3d. From their smoothness and softness they are removed without force, and produce no abrasion or irritation.

4th. They may be medicated with morphia, iodine, or anything *soluble in water*, but do not absorb alcoholic solutions or glycerine. After being so charged, they may be dried and kept for use an indefinite time.

5th. They do not become putrid, and therefore poisonous, as do sponge tents, and may therefore be retained twenty-four hours or more with impunity.

6th. The black, ovoid laminaria, from the Bay of Fundy, is much preferable to the other varieties yet brought to our markets, and free from the objections he has seen made to laminaria by some writers.

7th. The laminaria will be found of great benefit in obstructive dysmenorrhœa, if introduced a few days before the menstrual period, and also in cases of uterine catarrh connected with contracted cervix; they prepare the way well, too, for all intra-uterine medication. In either case, if softened in hot water before introduction, they rarely produce any pain or irritation.

8th. He thinks it better to insert several small tents than one, as the small ones expand more rapidly than the large ones.

THE FALLOPIAN TUBES.—Up to the seventh month of fœtal life both tubes are of equal length; from that time, however, the growth of the left is a little less than that of the right. The average result of 10 examinations of girls who died before puberty was as follows: The right tube measured 5.98 cm. in length, the left, 5.7. The average of 9 examinations of virgin women who died between the ages of 16 and 81, was 9.5 cm. for the right, and 8.5 cm. for the left tube. After the menopause the oviducts may grow from 2.5 to 4.5 cm.

During the active period of the sexual organs, the difference in length between the two tubes is less marked; the average of 22 examinations in married women under 45 years of age gave, for the right 11 cm., and for the left 10.9 cm. After menopause, however, the difference is striking, being in 12 women examined between 46 and 80 years, 9.75 cm. for the right, and 9.1 for the left.—*Am. Jour. of Obstetrics.*

A CASE OF A SUPERNUMERARY TESTICLE.—In "Holmes' System of Surgery," it is stated that the question of supernumerary testicles may be dismissed with the statement that there is no clear evidence of one ever having been met with.

D. Thomas Kennard, of St. Louis, Mo. (*Med. Archives*), relates a genuine case, occurring in a patient 43 years old, whom he has known intimately for ten years. Repeated physical examinations enabled him to feel three distinct glandular bodies of equal and unusual size in the scrotum; one upon the right side in its natural position, and two upon the left, one above the other, apparently connected by the same cord, but entirely distinct from each other, and a considerable space intervening between the two. Each body has that tense, elastic, peculiar feeling, characteristic of the testicle, and compression produces that sickening pain which pressure upon any other portion of the organism fails to produce. The supernumerary testicle is not free in the scrotum, as most probably any abnormal tumor simulating it would be, and it is now, and always has been, of equal size with the other testicles.

SCARLET FEVER.—Dr. L. Wood, of Ausable Forks, N. Y., writes:—

"My experience of scarlet fever, which has prevailed in this place and adjacent country for the past year, coincides with that of Dr. Zeigler, of Carlisle, Penn. My treatment is much the same as his. Potass. chloral where the throat symptoms are mild, but in severe cases I have found much benefit from a strong gargle of tinct. ferri chlor., with quinia sulph. in solution, and also administered internally. In one-half of my cases there was inflammation of the glands of the throat, which usually subsided to an application of liniment composed of sweet oil and ammonia well bathed in with heat. In only a very small number of cases did suppuration occur. The tepid bath in my practice has been serviceable. Where the febrile movement has been intense, and the pulse very rapid—one hundred and sixty and upwards — I have employed the veratrum viride to the extent of nausea, with prompt amelioration of all the symptoms. Very many cases of general dropsy occurred, with uræmia, for the relief of which I have depended mainly upon elaterium, even in the youngest children. My experience as to the contagious nature of the disease accords with the Doctor's, and I think that our percentage of fatal cases is quite as small as his."

A NOVEL CASE AND ITS TREATMENT.—S. J. Cobb communicates the following to the *Nashville Journal of Medicine and Surgery*:—A lady having lost, at the age of twenty, all of her upper teeth, except the roots of the second left superior molar, over which she had worn a plate for ten or twelve years, called upon a dentist to have the plate refitted. He suggested the propriety of having the roots removed, and in endeavoring to do so pushed them up into the antrum. In examining into the case closely, he found, from necrosis and exfoliation, not only the floor of the antrum covering these roots destroyed, but a portion of the ethmoid and inferior turbinated bones, making an opening sufficiently large for their roots to pass into the nasal fossa, from which they passed out at the nose. There had been a copious fetid discharge through the nose for five years, following erysiplas of the face. After removing all the necrosed bone, a sponge saturated with two parts of carbolic acid and one of tincture of iodine was passed well up into the parts. For two or three days the discharge was increased, but soon decreased, and at the end of twenty days entirely ceased.

AN IMPROVED METHOD OF PLUGGING IN EPISTAXIS.—It is generally expected when the anterior and posterior nares are plugged, that a clot forms on the floor of the nose which compresses the oozing vessels. M. Fano, of Paris, uses the following method:—Instead of tying a pledget of cotton to the free end of the thread, he ties a series of pledgets along the string, as papers are tied to the tail of a kite. The string being now pulled from the nasal end, is made, by a little management on the velum, to pass behind the latter with its four or five pledgets, until the latter are fairly lodged in the nose, the last pledget occluding the aperture of the posterior nares. The front may be plugged as usual. The whole is left four days.—*Lancet.*

BROMIDE OF POTASSIUM IN LEUCORRHŒA.—Dr. A. H. Kinnear reports (*Chicago Medical Journal*) twelve well-marked cases of leucorrhœa, none of which were of less than six months' standing, where bromide of potassium was administered with excellent success in doses of grs. xx twice a day. Under this treatment the disease yielded in a majority of cases in one month. He also gave the remedy in a case of gleet, which resulted in a perfect cure in the course of a week.

MEDICAL PSYCHOLOGY.

IN giving place to our esteemed correspondent "T." we do not wish to be committed to his opinions, for, on the contrary, we do not agree with him. No one, we believe, desires or proposes to make metaphysics, or psychology proper, a part of the curriculum of medical study, as our correspondent seems to suggest; and he is further at fault, we think, in assuming that the clinical study of insanity, as a disease, has so far failed as to be abandoned, as we will presently show.

There is nothing connected with human health that an accomplished physician ought not to study, and to have every facility for studying. Until within a few years, the mass of general practitioners of medicine have known little or nothing of insanity. They have hardly considered it a disease within their scope of study, but have rather regarded it as a phenomenon, like witchcraft or somnambulism; something to be speculated on for curiosity or melancholy amusement, instead of a bodily disease capable of being handled, modified, and cured by their art. If it be a disease, as it is, it certainly falls within the province of medical observation, study, and treatment; and it is therefore worthy of a place among the proper accomplishments, if not the absolutely necessary qualifications of the medical practitioner.

The importance of teaching in medical schools, and of the clinical study of insanity by medical students, is sufficiently evident by the practice and testimony of conspicuous names in the profession here and abroad.

The annual addresses to the Medical Society of the State of New York, in 1868 and 1870, by Dr. Gray of the State Lunatic Asylum, and Professor White of the Buffalo Medical College, take bold and strong ground on this subject, which appears to have been generally approved. The State Society unanimously passed a resolution "expressing the necessity of making didactic teaching and clinical instruction in insanity and all other cerebral and nervous diseases, obligatory as a part of the curriculum of study in our medical colleges."

In November, 1869,* there was a discussion of this subject, by the Medico-Psychological Association, meeting at the Royal College of Physicians, in Edinburgh. Professor Laycock was Chairman, and brought the subject of "clinical teaching of insanity" before that body, and urged the "propriety of memorializing the managers of the Edinburgh Royal Infirmary, with a view to greater facilities being given than at present, for the clinical teaching of insanity." After some remarks, and quoting from the observations of Dr. Thurnan, Professor Laycock asks significantly:—

"But how was a practitioner to be taught, if he only followed the study of insanity theoretically? He therefore thought the meeting would do well to recommend to Managers of the Royal Infirmary to set apart wards suitable for the treatment of the cases forced on the institution, according to past experience; not to establish an asylum, but to have wards for the reception of those cases which must be forced upon the attention of a private practitioner, and have special provision for the instruction of the great body of medical students. Insanity was usually included in a course of medical lectures; but in the lectures he gave on the subject, he found it utterly impossible to teach without bringing the students in contact with the insane, and illustrating cases to them, and when he did so, he went to an asylum and saw, cursorily, the progress of mental disease. The various causes of mental disease ought to be made a subject for the examination of students. In concluding, the learned gentleman referred to the increase in the number of cases of insanity, and said he thought the members of the association would do service to the public, and greatly advance the interests of medical science, by adopting resolutions to the effect, that provision should be made for clinical instruction in the classes of cases received in the wards of the infirmary to which he had referred; that medical students should be required to attend hospitals for the insane, and that there should be an examination of each in that special department of science, to see whether he was fitted for the performance of his important duties.

"Dr. Sibbald (having been invited by the chairman to give some information with reference to the system of instruction in mental diseases adopted at Berlin) said, that after the manner in which the subject had been treated by the chairman he had really nothing to add. He certainly thought it would be a great advantage, were they to do anything which would have as its result the association of diseases exhibiting mental symptoms of any other kind, and that they should, as far as possible, identify the teaching of their special department of medicine with other branches of medicine, as being a necessary part of the whole. He thought that from the manner in which the subject was taught in Berlin, it had perhaps arrived there at the most perfect form which was known at present, of teaching insanity as a branch of medicine. Professor Westphal had under his charge wards in the Charité at Berlin, devoted to diseases of the nervous system, not complicated with symptoms. He had also wards into which were received diseases of the nervous system exhibiting mental symptoms—that was to say, as they would ordinarily name them, cases of insanity. The wards into which the insane patients were received, were practically an asylum, with full asylum administration in so far as that was necessary for the

* *Journal of Mental Science*, January, 1870. London.

treatment of acute diseases. Only recent cases were admitted, and consequently the students saw the cases which they were most likely to meet with in practice. When cases threatened to become chronic, they were transferred to the district asylum.

"He therefore having been impressed with the importance of teaching in the way in which it was carried on in Berlin, had very great pleasure in supporting the proposal of the chairman, with this exception, that perhaps their function would be more properly performed if they confined themselves to saying that clinical teaching of insanity should be made an imperative part of medical education."

The discussion terminated in the unanimous adoption of the following resolution:—

"*Resolved*, That this meeting desire to express a strong opinion of the necessity of making clinical teaching of insanity imperative in every medical curriculum, and request the Secretary to send a copy of this resolution to the Medical Faculties and University Courts of Scotland, the Boards of Examiners in the Universities of Scotland, and the members of the General Medical Council."

Dr. Gray, in his annual address referred to, gives a summary of the efforts made both in this country and in Europe in regard to the study of insanity, which we condense.

"I am well aware that this subject of extending the course of medical training to embrace the study of insanity is beset with difficulties; but they are not insurmountable. . . . . Dr. Benjamin Rush probably gave the first lectures on the subject. In 1791, he was called to the chair of the Institutes of Medicine and Clinical Practice in the University of Pennsylvania, and was one of the hospital physicians. He delivered lectures to the students of the university on insanity, with clinical instruction as a part of his course. This was continued till 1812, when his lectures were published—'an elaborate work which had long been impatiently expected.' (*Encyclopedia Britannica.*)

"Esquirol, in France, delivered lectures to his pupils in 1810, but he was not associated as a teacher with any of the schools of medicine.

"Sir Alexander Morrison delivered lectures in Edinburgh and London for many years, says his son, 'to the members of the medical profession, and to such other gentlemen as signified their wish to attend them.'

"Dr. A. L. Sutherland, at St. Luke's Hospital, London, delivered lectures on the pathology and treatment of insanity, from 1843 to 1855. More recently (1853) Dr. George Johnston delivered lectures on the subject before the Royal College of Physicians, in Edinburgh. Dr. Daniel H. Tuke has for several years delivered lectures on psychological medicine at the York School of Medicine. Dr. Guislain began in 1849 to deliver clinical lectures on insanity in the Insane Asylum of Ghent, before the students of the University in that city; Baillarger and Ferrus also in Paris as early as 1854; Dr. Pliny Earle in this country before the Berkshire Medical School, Massachusetts; and Dr. Tyler to a few pupils at Cambridge, Massachusetts."

It was reserved for Professor Griesinger, in Zurich, Switzerland, and now of Berlin, to bring to those great schools of medical learning, the full realization of the importance of this subject to general medicine, as well as psychology, and to secure full instruction in this branch, in connection with the teachings from the chair of pathology. "Thus," says Griesinger, "has been established its true position as a proper and profitable subject of study, and as one demanding alike systematic and clinical instruction," and "its recognition as a regular portion of medical education." This distinguished pathologist maintains, with his characteristic comprehension of the whole field of medical research, that medicine is one study, and that the interdependence of all its branches forbids the successful study of any dissevered from the whole, and that "the lesions of the brain and nervous system constitute the real subjects of treatment, and their discovery is the true province of diagnosis." "Thus," he declares, "is psychiatrie intimately allied with the whole subject of cerebral and nerve pathology. What psychiatrie is, is understood by him alone who comprehends this alliance; and he only who has been duly instructed in the difficult questions of diagnosis in cerebral and nerve diseases, can embark on these problems respecting mental disorder, with hope of satisfactory results." Professor Griesinger in a recent letter says: "I remain firmly in the opinion that it is an absolute necessity to provide in every medical school for clinical instruction in this branch of science, equally important for the welfare of the patients and their families as for the forensic duties of the profession. I remain also in the opinion that mental diseases are only a part of cerebral and nervous diseases, and that it is most convenient to connect intimately the study of mental science with the study of the pathology of nervous diseases.

"Clinical teaching in psychiatrie is not merely a future possibility, but an existing fact in several medical schools in Germany: the difficulties are by no means so great as many people think; nay, the carrying on the work of this teaching is very easy, if only men of good will and experience are charged with the execution.

"Since my first lecture of 1863, I was constantly occupied in this line. At Zurich, in the summer courses of 1863 and 1864, I had a very satisfying psychiatrical clinique, only in an old and small asylum, but with really great advantage for the pupils. Since the nearly three years I am at Berlin, my psychiatrical clinique had an augmenting success every year, and my results have been very satisfactory. The Prussian Government accorded me at my proposition, when I entered its service, the invaluable institution of a special division of the insane patients. So I can unite *de facto* the study of the two intimately connected branches, and I give now in the winter course regular lectures on nervous diseases with clinical demonstrations in each lesson. I think this way the best for the professor and for the pupils, and, I may say, for the advancement of science; but if, however, such a combination of the two cliniques may be impossible at another place, then I cannot but strongly recommend to carry out the clinical teaching of psychiatrie alone."

"Within a year, the Bellevue Hospital Medical College of New York, has established a chair of 'Diseases of the Mind and Nervous System,' to which Dr. William A. Hammond has been appointed, and the 'College of Physicians and Surgeons of New York' has appointed Dr. D. Tilden Brown, of Bloomingdale Asylum, lecturer on Psychological Medicine and Medical Jurisprudence. Thus the initiatory step has been taken in this country."

It seems to us that the sort of practice and study thus recommended by distinguished professional gentlemen is not liable to the suspicion or the reproach of an attempt to fasten metaphysical abstractions and subtleties upon a profession which naturally abhors them; and that the spirit in which the effort is urged

and prosecuted is eminently practical and deserving of encouragement rather than check.

We learn that the Board of Education of this city have recently introduced a new idea into their department, which bids fair to become, at no distant day, one of marked importance. For several years past the necessity for certain sanitary reforms in our public schools has been apparent, and various suggestions to effect the same have been made by those who were most familiar with the practical details of the school system; but because of a failure to appreciate their importance by those who controlled the schools, they have never yet been productive of any beneficial result. There is a prospect now, however, that a change for the better is to be effected. We are not familiar with the details of the proposed reforms, but among them may be mentioned the rules governing the absence of teachers through illness, the system of vaccination, the condition of the schools themselves as to heating, ventilation, overcrowding of pupils, etc., etc. The subject is one which every good citizen, especially parents of school-children, is or should be interested in, and we have no doubt it will become ere long one of practical interest in all our large cities. Dr. R. J. O'Sullivan, for many years one of the most active promoters of the welfare of the public schools, has received the appointment of Visiting Physician to the Board of Education, and under his surveillance we have no doubt great good will be accomplished.

We shall call attention to this matter at greater length hereafter, and meanwhile venture to express the hope that the profession will take an active interest in the proposed reform, and do all in their power to render it a practical success.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, November 23, 1870.

Dr. J. C. Hutchison, President, in the Chair.

Dr. Finnell exhibited the liver and uterus of a gin-drinking negress, aged 50, who died of anasarca. The former organ was the seat of marked cirrhosis, the latter of fibrous tumors.

FIBROMA UTERI.

Dr. Little also exhibited a uterus removed from a married female patient, aged 23, who had died the day previous to the meeting at Bellevue. In Jan., 1868, she was caught during her menstrual epoch in a rain-storm, and the flow was in consequence temporarily arrested. The attendant pain and inconvenience were relieved by a hip-bath, &c., &c. Three months after this she probably miscarried. She presented all the usual symptoms of ovarian disease on her admission, but three days after was seized with uterine hemorrhage, which ran her into such a typhoid state as to preclude the possibility of any careful uterine examination. She gradually sank and died, and during the last two or three days of her life she passed from the vagina some ragged degenerated material, which at the autopsy was found to fill the uterus, much enlarged in consequence. There were evidences of peritonitis in the neighborhood of the womb. Dr. L. was of the opinion that the mass was a degenerated fibroid. By request the specimen was referred to the Committee on Microscopy.

EPITHELIAL DISEASE OF THE MALAR BONE.

Dr. Little also exhibited the left superior maxillary and malar bones which he had removed, respectively in an interval of four months, from a woman forty-four years of age, for tumors in those localities involving said bony parts. A year ago last May the patient first began to have a discharge from the left nostril, coincident with which a growth appeared, which in a year more completely plugged the passage and projected through the external orifice. Dr. L. having seen her then for the first time, believed the growth to be polypous; but in attempting to remove it in the ordinary manner found it fleshy in consistency, and attended with so much hemorrhage as to necessitate plugging. She was afterwards sent to St. Luke's Hospital, where, after a consultation, it was thought advisable to remove the left superior maxillary bone. This was accordingly done in the usual manner, when not only the nostril but the antrum as well was found involved in the disease. The section was made through the zygoma, and a portion of the hard palate was left. The second operation, four months afterwards, was necessitated by the reappearance of a growth over the malar bone. This latter was mainly confined to the soft parts in the neighborhood of the bone, and was found on examination by Drs. Delafield and Buck to be epithelial in character, while the first was supposed to be simply papillary.

A third specimen by the same gentleman was a portion of the head of the ulna, removed by operation from a lad fifteen years old, who sustained an injury of the wrist joint followed by inflammation, necrosis, fistulous openings, etc. The head of the bone referred to was involved in necrosis, as well as its articulating surface with the radius. Both of these portions, with the necrotic tissue, were removed.

EMBOLUS:—VEGETATIONS ON VALVES.

Dr. Loomis exhibited a specimen taken from a German woman, aged thirty-two, who was admitted into Bellevue Hospital on the 10th of Nov. Nine years before she had her first attack of rheumatism, three years ago her second attack, and a year ago her third attack. Each one confined her to her bed for two or three weeks. With these exceptions she reported herself as a perfectly well and healthy woman up to last May, when she began to complain of pain in her left side and a shortness of breath on exertion. She had also a cough, which was accompanied by rather a tenacious expectoration. Last August she was confined at full time of a healthy child. Since that time she had failed rapidly in health, so that on her entering the hospital she was very much emaciated. Her temperature was then 102°, pulse 100, and her respiration 30. She located the pain in her left side, over the region of her heart, and her expectoration resembled somewhat that of pneumonia.

On physical examination there was slight dulness on percussion over the posterior portion of both lungs as high up as the scapulæ, and over each lung there was a diffused bronchial respiration, most marked on the left side. There was an increase of vocal resonance, but there were no râles appreciated at that time. The apex of the heart beat to the left of the left nipple, the whole cardiac impulse was abnormally diffused, and was accompanied by a purring thrill. At the junction of the third rib, and just behind the sternum,

there was distinctly felt a pulsation synchronous with the cardiac impulse. The area of the heart on percussion was increased, showing it to be hypertrophied. On auscultation a distinct murmur was heard at the junction of the third rib with the sternum, having its maximum intensity at that point, and heard with, and after, the second sound. This was conveyed along the sternum downwards to the xiphoid cartilage. There was also another murmur, which was of a blubbering character, conveying to his mind the idea of vegetations, and heard before the first sound, and with greatest intensity at the apex. There was still another murmur following the first sound, and with it heard with greatest intensity at the apex, conveyed to the left, and heard behind the angle of the scapulæ. Dr. L. thought that he also heard a fourth sound at the base. From this time there were also pulsations in the carotids. From this time the patient lost flesh the more steadily. It should be stated that there was a node upon the forehead, and also several along the line of the tibiæ.

On the 15th of November, five days after her admission, it was noticed that the radial pulse in the left arm was felt very indistinctly, and that there was the same indistinct beat along the course of the artery until you reached the axilla. At the same time it was noticed that there was a loss of pulsation in the femoral artery, and in the common iliac below the bifurcation. Nov. 18th she was seized with a severe attack of dyspnœa. The House Physician, who examined her at that time, discovered crepitant râles over the posterior portion of both lungs. These râles, and râles of smaller size, were heard in a circumscribed area. The succeeding day these râles had almost completely disappeared, giving place to the same diffused bronchial respiration heard at the time the patient was admitted into hospital. Nov. 20th she became delirious. There was then noticed a complete loss of the radial impulse; in fact no pulsation could be detected below the axilla of that side. The pulsations in the arteries of the right side were good. Gangrene had commenced in the foot, the result of the continued interruption of the circulation to the part. The temperatures in two sides varied materially in consequence of the differences in circulation. In the right axilla it was 102½°; in the left, 100°; in the right inguinal, 101°; and left, 97. This difference in the temperature continued until death. The delirium continued, the patient passed into a typhoid condition, the heart's action became irregular and intermitting, and on the evening of the 20th she became unconscious and sank.

On opening the cavity of the cranium there were found in the arachnoid about four ounces of fluid. The arachnoid itself did not present anything abnormal. The left middle meningeal artery was plugged. There were no points of softening in the brain substance. The pericardium was found attached to the pleura, and the two surfaces were agglutinated to each other. The pericardial sac contained about twelve ounces of fluid. There were firm bands of adhesion between the two surfaces of the pericardium, and these bands were of considerable length at certain points. The right side of the heart was normal; the left ventricle was, however, very much dilated, its walls hypertrophied. Mitral and tricuspid valves were found thickened, and their edges at different points seemed to be adherent. On the ventricular surface of the aortic valve was a vegetation the size of a pea, standing out very prominently. The mitral valve contained vegetations on both its surfaces. There must have been interference in the passage of the blood from the auricle into the ventricle, also obstruction in consequence of vegetations on the ventricular surfaces of the mitral valve. The axillary artery was plugged with fibrine, as was also the abdominal aorta about two inches above the iliac bifurcation. This plug extended into the femoral, but only partially obstructed this vessel. The mesenteric artery was also plugged up from its origin to an inch and a half.

The lungs were firmly adherent throughout, and the cavity of the left chest contained considerable serum. The right lung was œdematous. There were no evidences of pneumonic inflammation in either lung. In the kidneys were yellow infarctions, as was also the case with the spleen, and one of the arteries of the latter organ was plugged.

The interest of the case was mainly in the points of diagnosis.

Dr. Briddon asked if there was any difference in the character of the bruit after the embolus occurred?

Dr. Loomis was not made aware of any such difference.

Dr. Briddon remarked that he met with a case of embolus of the cerebral artery ten years ago, in which a difference in the bruit was very manifest after the accident.

Dr. Loomis asked if hemiplegia might not have had something to do with the alteration in the character of the bruit?

ANEURISM TREATED BY LANGENBACH'S METHOD.

Dr. Briddon exhibited a specimen of thoracic aneurism, the chief interest of which was in the treatment. The patient was a very intelligent German apothecary, who first presented himself for treatment in Jan. last. He then had all the physical signs of thoracic aneurism of the ascending arch—a pulsating tumor to right of sternum, and a characteristic bruit—and was suffering from the effects of pressure. He was placed under the treatment advised by Prof. Langenbach, viz., hypodermic injections of ergotine. During the period of observation of the patient, from the first of January until the day of his death, one hundred and fifty injections were administered, averaging two grains each. Four grains were sometimes injected, when the symptoms of ergotism seemed to show themselves. The preparation was Merk's, and was generally dissolved in glycerine, alcohol, and water, and a quantity of the fluid equal to twelve drops thrown in at once. The immediate effects of the injections were markedly beneficial in relieving the unpleasant symptoms attendant upon pressure; but in view of the uncertainties attending measurements in such cases, no trustworthy assertions could be made. During a period of three or four weeks in September, the treatment was intermitted in consequence of a severe attack of pleurisy on the right side with effusion. At that time large doses of iodide of potassium with digitalis were used with benefit to the complication, but with no marked good result upon the aneurismal symptoms. The injections did not appear to produce any irritation.

Death occurred suddenly from rupture of the sac. At the autopsy eight or ten pounds of coagulated blood were found in the right pleural sac. The rent was a large one. The aneurism was of the fusiform variety, commenced immediately above the aortic sinuses, and involved the whole of the ascending portion of the arch, and a small part of the transverse portion. He remarked that no effect of treatment was noticed upon the aneurism.

Dr. Post stated that fusiform aneurisms were, from their very nature, the most unfavorable for medical treatment, in consequence of the uninterrupted and strong current of blood through them. There was no

chance for the formation of a coagulum unless the opening between the artery and sac was small, as in sacculated varieties.

Dr. Briddon stated that Langenbach had reported two cases of cure of aneurisms of the extremities by injection of ergotine; in one upon the upper extremity one operation was necessary. These results were not, however, substantiated by autopsical examinations. Langenbach's theory was based upon the well-known action of ergot upon the unstriped muscular fibre. If such a theory were correct, he should expect to find some marked result in a sac completely surrounded by these fibres.

Dr. Van Geison asked if the pulse was lower after each injection?

Dr. Briddon answered that such was not noticed to be the fact. In answer to a question from Dr. Hutchison, he stated that the injections were administered over the tumor.

DRY AMPUTATION—SENILE GANGRENE, ETC.

Dr. Sayre presented a portion of the popliteal artery removed from a very old colored woman, whose leg was amputated at the knee-joint for gangrena senilis of the right foot and ankle. The amputation proved to be a perfectly dry one in consequence of the plugging of the main artery immediately above the section. After the removal of the plug the artery was secured in the usual way. One week after the operation the patient was doing well.

Dr. Newman remarked that the dry amputation, being the result of a plug, gave a much more favorable prognosis to the case than if that condition was due to a disease of the arterial coats. In this connection he referred to a dry amputation in which such a condition of things existed, and death resulted in a few days after the removal of the limb, from an extension of the gangrene in the stump.

Stated Meeting, Dec. 14, 1870.

BACONY LIVER.

Dr. A. L. Loomis, Vice-President, in the Chair.

Dr. Rogers exhibited a specimen of liver which resembled bacon in appearance. It was removed from a man who had died of phthisis. He believed that the morbid condition of the organ was due to an albuminoid degeneration.

CYSTIC TUMOR OF BREAST.

Dr. Sayre presented a tumor which he had removed from the left breast of a lady thirty-four years of age. She first presented herself about ten days before the operation. There was then a small tumor about two inches from the nipple, very hard and exceedingly painful. It had all the feeling of scirrhus, although there was no retraction of the nipple. The diagnosis was not positive, but the suspicions were firm enough to warrant an immediate operation. Dr. Hamilton also saw the case, and, although he was not sure of the nature of the disease, advised an amputation. The operation was accordingly performed Dec. 11. After removal the tumor was found to be simply a very firm and distended cyst, the size of a hen's egg, having nevertheless the exact feel of a scirrhus. There were a number of smaller cysts scattered throughout the breasts, all of the same character.

RESECTION OF CERVIX FEMORIS.

Dr. Sayre exhibited also a lad upon whom he had performed exsection of the head, neck, and trochanter major of femur five years ago. The limb was half an inch shorter than its fellow, but was equally well developed, and with the exception of a limited fibrous anchylosis, was as useful. The patient, however, could walk well, and even run with ease. He had been admitted to Bellevue, and after the operation had been performed it was found by the authorities that he was not a fit subject for treatment, and was hurried to his home in the country during a snow-storm, there being only opportunity for the application of the wire breeches. His mother, after their arrival home, took sole charge of him. The good use of the limb, even under such circumstances, was due, in his opinion, to leaving the periosteum intact. The wound had been stuffed with oakum simply.

FATTY DEGENERATION OF PLACENTA.

Dr. Le Baron Hart, presented a specimen of extensive fatty degeneration of the placenta, with the following history:—The patient was a lady, married ten or twelve years. She had two healthy children at full term, but during her third pregnancy she strained herself very severely. An attack of metritis followed, and then a miscarriage at three and a half months. Since then, six or seven years ago, she has had ten other miscarriages, generally between the third and fifth months. In that connection he exhibited another placenta, the subject of slight fatty degeneration, discharged at full term by a woman married seven years, who had had several miscarriages. After the last abortion she had been placed under treatment for metritis and ulcerated cervix, and was completely cured. Soon after this she became pregnant, and was delivered of a healthy full-grown child, since which she has had the second, to which the placenta exhibited belonged. He was assisted in the microscopical examination of both specimens by Prof. Jacobi, who agreed in the opinion that the causes for the miscarriages were explained respectively by the lesions discovered.

CALCULUS IN THE NEGRO.

Dr. Mason exhibited a calculus which he had removed by operation from the bladder of a colored man, aged sixty-four. The specimen was interesting on account of its rarity in a negro, and as being the first of the sort met with in the Colored Home for a period of thirty years.

DIVERTICULA OF BLADDER, ETC.

Dr. Hinton presented the bladder, left kidney, and spleen, removed from a man aged sixty-eight, who had been under his observation for the past five or six years. He had difficulty in passing his water during the most of that period. He was obliged to urinate very frequently, and generally took a long time to accomplish the act. Dr. H. was called to him November 30, and found that he had not passed water, notwithstanding frequent attempts so to do, for ten or twelve hours. The day before he had some œdema of the lids, and this œdema had in that time extended to the arms and lower extremities. On examination a solid tumor was discovered in the right iliac fossa, about eight inches long by four in width. This swelling, the patient stated, had existed for two or three years. An attempt was made to relieve him by the catheter, but failed, notwithstanding the instrument was passed its full length. On withdrawing it its eye was filled with blood, which circumstance seemed to be explained by a granular condition of the urethra. Dr. H. was satisfied that the instrument, because its point was fixed, did not enter the bladder. Another attempt was made to guide the point of the instrument by means of the finger in the rectum. This manœuvre likewise failed. No prostate could be felt, and it occurred to the doctor that the bladder had been drawn high up by the ad-

hesions to the tumor. After a while the patient passed six or eight ounces of his own accord. His dropsy increased after that, but as his bowels acted promptly to hydragogues no further attempt was made to relieve him by catheterism. He was quite comfortable, passing small quantities of water at a time, until the evening of the 6th inst., when he was seized with hiccough, intense pain in his bladder, and great smarting on urination. An anodyne was administered, and the patient was advised to have warm fomentations applied, and to sit over hot water. That night he was seized with a convulsion and died.

The autopsy was made the afternoon following. Everything being flaccid, the catheter was passed without difficulty, and a pint and a half of urine was drawn off. The bladder was found bound down by adhesions, and communicating with its cavity were five good-sized diverticula, which made collectively the tumor in the iliac region. The prostate was much enlarged and drawn out of reach by the adhesions. The left kidney was sacculated, its pelvis being thirteen or fourteen times its normal size. The corresponding ureter was also much enlarged. From the lower part of this kidney there came what appeared to be a second ureter, but no thorough examination had been made to establish the point. The spleen had a dense capsule, had a pultaceous pulp, and was subject to calcareous degeneration. The bladder held just two quarts of fluid.

Dr. Jacobs believed that the diverticula were due to localized inflammations weakening the coats at those points, and causing them to dilate in the subsequent efforts to void the urine.

Dr. Hinton remarked that this was possible, and the specimen was referred to the Committee on Microscopy that the question might be settled.

MISCELLANEOUS SPECIMENS.

Dr. Finnell presented several specimens. The first consisted of a portion of the lungs, the uterus, and heart, taken from the body of a colored woman, aged thirty-five, who died in a hallway from acute tuberculosis. The aortic valves were thickened and insufficient, the lungs were studded with tubercle; but, strange to say, notwithstanding she was a negress, the uterus was free from fibrous growths. The second specimen was an extensive epithelioma, which, commencing at the left angle of the mouth, involved the larger portion of the upper lip in continuity. It was removed by operation at St. Vincent's Hospital. A third specimen was an axillary tumor, supposed to be an enlarged gland, removed at St. Vincent's Hospital from a female aged twenty-two. A fourth specimen was a fatty liver, from an intemperate female, showing localized fatty deposits in its substance.

The fifth and last specimen consisted of the kidneys and portion of the uterus, removed from the body of a woman aged 49, who, notwithstanding the existence of carcinoma uteri, had been treated by five different physicians for phthisis. The kidney was the seat of cystic degeneration, and the uterus was extensively involved in cancerous disease, as well as the contiguous parts. The point of interest bore upon the question of diagnosis and skill in auscultation, the lungs being perfectly healthy! Another point was interesting in this connection, and that was that two of the physicians were members of the Society.

CANCER OF FIBULA.

Dr. Bradley presented the foot and portion of the leg, removed by amputation from a lad fifteen years of age, who, a year ago last August, fell over a croquet wicket and injured his fibula. Almost immediately after he was seized with severe pain at the point particularly injured, three inches above the external malleolus. This condition of things continued at intervals for months, not, however, confining him to the house. The family physician advised a free and deep incision, which was objected to, and not really done until the following June, by Dr. Bradley. He found, on cutting down upon the part, diseased bone, and removed the same, giving directions that the patient should go to the country and keep the wound open until autumn. In the course of the summer Dr. Bradley was sent for, and found a semi-solid, fluctuating, and malignant-looking tumor, the size of a man's fist, in the situation of the operation. In the second week in September he made a V-shaped incision over the part, and removed a handful or more of broken down necrotic tissue. He scraped the bone in the vicinity and discovered a united transverse fracture of the fibula. It was impossible, on account of the hemorrhage and prostration of the patient, to remove all the dead bone, and a portion was accordingly left behind the tendo-achillis. The wound filled up until it was nearly closed, when a fungoid mass commenced to show itself in its bed. In consultation with Dr. J. R. Wood the mass was decided to be cancerous, and amputation being advised was accordingly performed. The patient by last accounts was doing nicely. There was no hereditary predisposition to cancerous disease, unless it be allowed that the great-grandmother, on the father's side, had cancer of the breast, and lived to be eighty-six years of age.

AMPUTATION OF BREAST, ETC.

Dr. Howard presented the right breast of a female, aged 45, which he had amputated for malignant disease. In this instance, although the disease was otherwise well pronounced, there was no retraction of the nipple. The wound healed almost entirely by the first intention. He merely exhibited the specimen for the sake of adding it to the experience of others in determining the best method of treatment; and in this connection he remarked that he had removed two breasts for scirrhus, one one year, and the other two years ago, neither, up to the present, showing any tendency to a return of the disease.

GALL STONES.

Dr. Freeman presented a ruptured gall-bladder containing a single biliary calculus. The case was interesting to him, as during its progress it presented no symptoms indicative of the true character of the disease. There was no jaundice from first to last. The patient was a lawyer, forty-five years of age, whom he was called to see on the 27th of last month, suffering from what appeared to be a congestive chill, with a pulse of but 40. The day before he had eaten pretty heartily of fresh fish, which he thought had disagreed with him. He complained of severe distress, and had vomited considerably. In spite of stimuli, reaction was not fully established until the following day, when the pain in the stomach became more severe and seemed to centre in the right hypochondriac region. The pulse then ran up to 120. This continued with spasmodic pain for three or four days; and early in the morning of December 1, the pain being more severe than usual, it was relieved by a hypodermic injection of morphine. There was not much pain on pressure, and from the absence of all symptoms referable to the liver, renal colic was diagnosticated. The day following delirium appeared, and death occurred within twenty-four hours. He was seen in consultation by Dr. Corey; but there was an obscurity connected with the diagnosis until the autopsy was held.

On opening the peritoneal cavity there were found

evidences of local peritonitis in the neighborhood of the gall-bladder, while the recto-vesical sac contained two or three ounces of pus inclosed in a croupous membrane. The peritonitis was due to a rupture of the gall-bladder. There was no abdominal distension at any time.

AMPUTATION OF BREAST.

DR. LITTLE presented three specimens. The first was a breast, removed from a lady patient at Saint Luke's on the 28th of last Nov. She was twenty-five years of age, and for the past two years had noticed a tumor in the right breast near the nipple. There was very little, if any pain. The tumor gradually enlarged, and for the past few months she had been under the care of Dr. Burral, who had been treating her with carbolic acid. On examination the breast presented the ordinary appearances of scirrhus. After the amputation of the organ it was found to contain two distinct tumors, one benign and the other malignant. Dr. Delafield had examined the specimen, and would report upon the same.

REMOVAL OF TESTICLES.

The second specimen was a tumor of the testicle, removed from a patient thirty years of age, who injured his testicle six or seven years ago. Some inflammation and pain followed, but soon passed off. He did not notice any inconvenience until three years ago, when the left testicle began to enlarge, producing in time such severe dragging pains as to necessitate anodynes for relief. On admission the affected testicle was the size of the double fist, and presented very much the appearance of a hydrocele. The lower portion was hard and opaque, the upper soft, fluctuating, and translucent. The operation was performed in the usual manner. Specimen examined by Dr. Delafield.

The third specimen was also a testicle, removed Nov. 29th. This patient was sent to the hospital by Dr. Caro. Six months ago an injury was inflicted upon testicle by rowing, which caused a transient swelling and pain. Three months ago the pain recurred, attended with swelling and suppuration in the most dependent portion. This latter portion discharged itself, and a fungous mass protruded, giving the appearance of a scrofulous testicle. This was also examined microscopically by Dr. Delafield.

DR. LITTLE related the history of an operation of removal of two small tumors from underneath the sterno-cleido-mastoid muscle of a female patient of St. Luke's Hospital. The growths were less than a year in making their appearance. One tumor was situated under the posterior edge of the sterno-cleido-mastoid, and the other under the anterior edge, beneath the angle of the jaw. The last involved the sheaths of the vessel, and could not be removed entire, notwithstanding a very careful dissection had been made. Subsequent to the operation erysipelas developed itself, and the patient died thirty-six hours after the operation. Previous to the operation, although the woman appeared in good health, directions were given to examine her urine, but they were unfortunately neglected. When the urine was drawn off by catheter during the coma, it was found to be albuminous, and to contain casts. This condition of things, in all probability, explained her death.

CANCER AND ADENOID TUMORS IN SAME BREAST.

DR. DELAFIELD remarked that the first specimen of Dr. Little's tumors of the breast was one of considerable interest. The upper tumor connected with the nipple was an example of cancer, but different from the ordinary form. It was composed of a number of small lobules, separated by dense septa apparently formed of fibrous tissue. The lobules were composed of alveoli filled with cells. The alveoli in some of the lobules were not merely round or oval, as usually seen, but they presented somewhat the appearance of long canals filled with cells. Sometimes these lobules were so narrow as to contain two or three cells abreast, while others were very much broader. The lower tumor is composed entirely of a dense stroma of fibrous tissue, and imbedded in it at moderate distances are granular follicles resembling those of the normal mammary gland. Then we find one or two small nodules, which have the same composition as the cancerous tumors, proving that the adenoid tumor has become infected with the cancerous degeneration of the first. The occurrence of these two forms of tumor in the same breast, although rare, has been observed by others; but Dr. Delafield believed that it was very rare, when they do occur, for the glandular tumors to become the seat of any cancerous degeneration.

The second specimen of Dr. Little, the first testicle, was merely an example of true cancer, and only interesting as to the length of time it took in growing.

In the third specimen the testis and epididymis are enlarged and altered, and both present the same changes. The albuginea is quite dense by a deposit of white fibrous tissue, which extends inwards in the substance of the epididymis and testis. These white bands consist of white fibrous tissue and cells. If it were not for the fungoid protrusion the microscopical appearances would resemble more a syphilitic inflammation than anything else.

The fourth specimen spoken of by Dr. Little was merely of interest as regards the apparent idiopathic development of epithelial cancer in the gland, although this assertion could not be positive, as other parts of the body, *e.g.*, the larynx and trachea, had not been examined.

CATARRHAL PNEUMONIA.

DR. LEWIS SMITH presented the lungs of an infant that died at the age of four and a half months. The patient had for some time been subject to diarrhœa from entero-colitis, and had been in an emaciated state. About three weeks before its death it had a slight attack of bronchitis, but no marked acceleration of the respiration, and no marked change in the condition until four hours before its death, when it was found suddenly sinking. On making the post-mortem examination a moderate amount of bronchial inflammation was found, the chief point of interest being the solidification in the posterior portion of the lower and upper lobe of right lung, and a very small amount of the same kind of solidification in the posterior portion of the left lobe, it being limited to small nodules some scarcely larger than a pea. He believed the pneumonia to be catarrhal in character, and remarkable in connection with the latency of the symptoms during life. Referred to Committee on Microscopy.

A second specimen was an enlarged heart and atheromatous aorta, removed from a debauchee who died of delirium tremens.

WHITE SOFTENING OF BRAIN.

A third specimen was one of white softening of left hemisphere of brain, removed from a hemiplegic female patient of Charity Hospital. This condition was supposed to be the result of an embolus, as branches of the middle cerebral artery were found closed from atheroma. The examination could not be made with a view of determining the exact situation of the plug. The heart was in nearly a normal state, but there was

a slight atheromatous deposit in the ascending portion of the aorta.

Dr. Fleet Speir, of Brooklyn, presented some specimens of arteries closed by means of a new instrument which he had devised.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Dec. 15, 1870.

Dr. H. D. Bulkley, President, in the Chair.

DISCUSSION ON DR. THOMSON'S PAPER. (SEE PAGE 531.)

Dr. John C. Peters: I have been very much interested in the tone of argument pursued by Dr. Thomson, as it is comparatively, or almost completely, a new one, and one which I am very slightly prepared to follow.

I regard the position which he takes about the classification of remedies according to the time required for their operation, as important and suggestive; and it is one which is now receiving timely corroboration in the labors in Analytical Pathology of Dr. Moxon, Physician and Pathologist to Guy's Hospital. [See *Medical Times and Gazette*, July 1st to December 1st.]

Dr. M. traces all disease not merely into the tissues, but into the *elements* of the tissues, which he divides into three great groups, viz.: 1st, The *cell-tissues*, or those made up of cells only, with nothing between them; 2d, The *intercellular* tissues, or those composed of cells, with an important quantity of material, or parenchyma, between them; and, 3d, The *tubular* elements, or those in which the original cells are prolonged or united into long tubes in which peculiar contents are found.

The principal cell-tissue elements are the *epithelium* blood-cells, fat-cells, cells of the secretory glands, cells of the blood-forming glands, and muscle-cells. All these are formed very rapidly in health; they multiply or proliferate quickly; then degenerate and as rapidly pass away. The majority of acute diseases are seated in them; thus, a very little irritation of the epithelial layer of the mucous membrane will produce an over-rapid production of epithelial cells, which loosen, fall off, and are succeeded by others, which are not perfectly formed, and do not retain their hold on the mucous surface, but slip away in the mucus, producing common catarrh, leucorrhœa, mucous diarrhœa, &c., &c.

When this quick or acute multiplication of elements occurs on a free surface, its effects are comparatively unimportant, because the products are able to escape; and when the irritation is allayed, or has passed off, healthy cells are reproduced, and the restoration is complete.

But when this multiplication or proliferation of epithelial cells occurs in glandular tissues, the consequences are rather more serious and tedious; the gland-tubes or follicles become choked up with epithelium, as in desquamative or epithelial nephritis or acute albuminuria; and in obstructive, or catarrhal, or epithelial hepatitis, or jaundice, from acute catarrh of the gall-ducts; and in acute gastric catarrh from choking up of the long, tubular glands of the stomach with ill-formed epithelial cells, &c.

Again, the blood-glands are very prone to simple multiplication of their elements. Thus the spleen is often actively engaged in making blood-corpuscles, and at other times equally actively engaged in breaking down a redundancy of them, and returning these elements to the circulation. The lymphatic glands often swell quickly from inflammatory irritation, brought to them by a lymph stream coming from an inflamed part, and as quickly subside; just as the mesenteric glands swell and their cell products become more numerous and pass on in the chyle stream, and so to the blood, where they produce a leucocytosis and a little fever. So the glands behind the bronchia swell up, in common pneumonia, to a large size. Still they do not suppurate, but quickly subside when the inflammation passes away. All these hypertrophic increases are generally of a transient character, corresponding to the temporary duration of the several cellular elements. If the normal nutrition of these cells includes their decay as well as their reproduction, and if this acute disease is merely an over-activity of their normal nutrition, then we should expect to find this overgrowth to be short-lived, so that when the cause of the augmentation is removed, the supernumerary elements decay and pass away, and the part returns to its normal volume.

The duration of all these disorders, and many other catarrhal, rheumatic, and febrile affections, is like the normal durations of the cellular elements, viz.: short-lived.

But the case is entirely different when the *intercellular elements* are primarily or secondarily involved. These are cartilage, fibro-cartilage, periosteum, membrane-stoma, submucous tissue, tendon-tissue, amorphous connective tissue, osseous tissue, and yellow elastic tissue. The great normal peculiarity of these tissues is, that they are slowly built up, and still more slowly removed; their changes are sluggish, for they are made to remain as they are, and maintain themselves in a more or less permanent condition.

They are made up of fully formed elements, and the causes which can give rise to a sudden increase or diminution in their quantity require to be more severe, and the causes of their slow increase must be prolonged.

If the new intercellular elements attain organization they remain obstinately and permanently.

If the increase of the intercellular elements is hastily excited, and in great quantity, an effect is produced which partakes of some of the characters of what is called "malignancy."

Thus, Mr. President, I have given you a short outline of Dr. Moxon's views. They are new, interesting, and suggestive; and although some of them are not quite satisfactory, I believe the majority of them are true, or at the least very plausible.

In the more transient forms of disease simple hygienic measures, or a timely diuretic, sedative, or cathartic, or diaphoretic, or emetic, depressant or expectorant, may be all that is necessary. But in the more obstinate varieties, long courses of alteratives, liquefacients, resolvents, nutrients, or tonics, will be required.

And here let me say a few words about one class of remedies touched upon by Dr. Thomson, viz., *Alteratives*. I believe that every remedy is, in some sense, an alterative; it must change or alter the action of the disease in some way in order to make any impression upon it. If it did not act alteratively, or differently from the action of the disease, it would only add so much more to it, *i.e.*, increase or aggravate it. In these simple truisms is contained the completest refutation of the whole of that specious system called Homœopathy. Again, the remedy must not only act differently from the disease, *i.e.*, alter, change, or modify it in the direction of health, but it must be given in doses large enough to produce these necessary alterations or changes. In this latter truism is contained a complete refutation of the whole absurd doctrine of infinitesimal doses.

Dr. E. R. Peaslee stated that it had often been remarked that the science of medicine goes around and

around in a circle; but every time it goes around it is on a higher plane than before, because we have advanced in pathology and diagnosis.

He hails with great satisfaction the advancement in therapeutics, and we must continue to go around and around in the circle until the right point is reached.

In regard to all the points presented by Dr. Thomson in his paper, he could not fully accept them, but accepts the paper in a general way, as the author is on the right track.

STATED MEETING, JANUARY 19, 1871.

DR. EDMUND R. PEASLEE, PRESIDENT, in the Chair.

THE retiring President, DR. HENRY D. BULKLEY, made the following introductory remarks:—

Fellow Members of the Academy:

Gentlemen—The vote just passed severs the last link of the pleasant chain which has bound me for the past two years to the position with which you have honored me—two years which, I trust, have not been without interest to us personally, nor without value in the promotion of the welfare of the Academy, whose interests we all have at heart,—years which have not been without labor, nor without responsibility on my part, both of which, however, have been lightened by the sympathy ever manifested in my endeavors to discharge satisfactorily the duties which have devolved upon me, and by the leniency shown in my shortcomings of duty, and the courtesy always manifested in my intercourse with you all, for which accept my kind thanks.

Thanks also for your response to the appeal which I made when I took the chair, the *key-note* of which you will perhaps recollect was *work*, without which nothing succeeds in any undertaking. To this response we owe the valuable papers and discussions to which we have listened, and by which we have been so instructed during the past two years, and the increased attendance which has shown that such labors have been appreciated.

Our register has shown no want of a quorum during the past two years, and no card has been issued during this period without announcement of work for the evening.

The report of our faithful and respected Treasurer exhibits a flourishing state of our finances.

Good feeling has everywhere prevailed, and nothing has occurred to disturb the harmony of feeling or of action.

Death has visited us with a sparing hand, only six of our number having been removed from among us. Alas! that my parting words have to be mingled with those of condolence on the departure of the lamented and faithful Bibbins, who has just been called away in the midst of his years and of his usefulness, whom we shall all miss as a tried and trusty officer of the Academy, and a most active and reliable fellow-laborer; a man of unswerving integrity, true to every trust, and the type of a Christian physician.

The accession of new names to our list of members has continued to increase our ranks, and our losses should stimulate us to run more diligently the race set before us while the opportunity is still spared us.

While I congratulate you upon what has been accomplished *within* our walls, I am able to add that the labors of those of our number who are charged with providing us with a local habitation are making successful progress. I need not dwell on the great importance to us, both as an Academy and as a profession in our city, of having a place which we can call our *home*, nor appeal to you again for sympathy and substantial aid in this movement.

It is a matter of regret that the sudden illness of the talented member who was to have favored us with an anniversary address the past year, deprived us of this privilege, and disappointed us in not being able to enjoy another production of this kind, worthy to be placed by the side of the one to which we listened with so much interest on the previous occasion of this nature.

I could have wished, gentlemen, that my appeal in behalf of filling up the ranks of the different Sections of the Academy had prompted to better results in this direction; that of Obstetrics still remaining the only active one of these organizations—an activity which has been rewarded by success, and for which it is entitled to our thanks. I trust that the renewed and increased efforts of my worthy successor will meet a more ready response.

While taking leave of the Academy, and of you individually, gentlemen, before proceeding to introduce my successor, permit me to congratulate you on the choice which you have made, by which you have honored the Academy in honoring him, and in whom you have a pledge of increased prosperity and progress in honor and usefulness. For such a result you have my sincere wishes, and will have my hearty co-operation.

All that remains for me before retiring from the platform, is to welcome and introduce to you the man of your choice as your next President.

To the President elect:

I have already congratulated the Academy, my respected Sir, on the honor it has done itself in the choice of you as my successor, and I now take pleasure in congratulating you on being the recipient of this honor.

It is a position, as you are aware, of *labor* as well as of *honor*, and I know that you accept the former with the latter. The record of your life bears testimony to your appreciation of the importance of *work;* and the eminence you have reached in both literature and science is an illustration of the success with which this is sure to be rewarded. In you, therefore, we have secured what the Academy wants, and always will want, a working man for its President. Allow me, then, to assure you of my best wishes for your success in this new post of honor and usefulness.

In conformity with the custom of my predecessors, I hand you a copy of the Constitution and By-Laws of the Academy, confident that you will interpret them wisely, and enforce them with discretion and impartiality.

Gentlemen of the Academy,—I take pleasure in introducing to you your President Elect, Dr. Edmund R. Peaslee.

The President Elect, DR. EDMUND R. PEASLEE, then delivered an interesting Inaugural Address. After thanking his associates for their kindness in selecting him as their presiding officer, and alluding to the honors conferred upon him in times past, namely, the Presidencies of the two other prominent medical societies of this city, mention was made of the sphere of action of the Academy in comparison with the other medical organizations. Each has its own sphere of action; but the distinguishing feature of this Society is, that it has a wider range, attention being paid to medical education and public health. He also stated that the Academy had a right to demand help from all its members. Following the review of the discoveries of Harvey and others down to the present time, the speaker urged the claims of medical science on medical men, and said that

the members must not forget that science has claims upon the old and young. The labors of others must be encouraged as well as their own, and medical science is advanced in *three* ways:—

First. By ascertaining and correcting existing errors.

Second. Much may be gained by collecting statistics, and publishing compendiums, monographs, etc.

Third. By making new discoveries. He would encourage the habit of thinking for themselves, and properly correcting the errors of others. Without independent thought on the part of Harvey the discovery of the circulation of the blood would have remained undiscovered.

In dwelling upon the *third* way to advance medical science, the Fellows were reminded that those who expect to be discoverers must be particular in searching out all that others have achieved, else their labors might be thrown away. If medical men wish to make additions to science they must have a definite point in view; but all honor to those who stumble upon a fact, even though something else was sought for. Three things are required when making discoveries: *First*, a higher faith as a moral element; *second*, perseverance; and *third*, courage and theory. It has rarely been the case that the true theory has been suggested at first when making a discovery. All methods imply labor. Those under forty years of age have done more than older men in the profession, and many discoveries made by young men were mentioned. The question was asked, Who have the leisure but young men? But the older men should not be excused on the ground of want of time, as many have achieved honors in their old age. Dr. Samuel Johnson learned Dutch at the age of seventy-one. Theophrastus commenced his "Characters of Men" at ninety. Young wrote his "Night Thoughts" at seventy. Age, then, does not detract from advancement in medical science, as Cullen was a splendid lecturer at eighty-three, and Hufeland at eighty. Dr. James Jackson, of Boston, was the pride of that city at a great age; and Drs. Nott, Clymer, and Post of our own city are noble examples.

In closing his remarks, he stated that want of time for advancing medical science is no excuse, and mentioned the fact that John Hunter always arose before daylight to advance himself. John Mason Good's celebrated translation was done in the streets of London while making calls on his patients; and Roux performed the operation of cataract upon six thousand cases, and yet had time to translate Latin, German, and other works.

In regard to the advancement of medical science, he contended that it was due to the regular profession alone, and that our science reposes upon the same basis that it has for two thousand years.

Finally, the want of a home for the meetings of the Academy was spoken of, and the President earnestly hoped that a suitable and noble building would be erected at no distant day, which would be an ornament to our city and a source of pride to the medical profession, around which all the societies could revolve.

The announcement was made that Dr. Gouverneur M. Smith will read, February 2d, a paper on "Diabetes Mellitus."

On motion of Dr. Roberts, the thanks of the Academy were tendered to Dr. H. D. Bulkley, the retiring President, and Dr. E. H. Janes, the late Secretary, for their untiring energy and ability in discharging the duties of their offices.

The Academy then adjourned, out of respect to the late William B. Bibbins, M.D., a prominent Fellow and Trustee.

Correspondence.

PSYCHOLOGY IN OUR MEDICAL SCHOOLS.

To the Editor of the Medical Record.

Sir—It is well known that many of our medical schools have recently added a professor of mental diseases to their list of teachers, and we have noticed the adoption of a resolution by the American Medical Association, at its last meeting, favoring the establishment of chairs of psychology. As we believe, however, that this addition of insanity to the curriculum of medical studies has been rather urged than discussed hitherto, a few words in regard to it may not be amiss.

Let us begin by declaring that no one is more ready than ourselves to welcome the current change in medical theory, by which the nervous functions are made of the first importance in our interpretation of disease. It is not unlikely that this change may at length bring about a return to the excessive use of metaphysical terms and abstract reasoning in medical discussions. But a diversion from the chemical and mechanical theories which have so long occupied the entire field of medical research is much to be desired, and the practical tendency must be to lessen the evils of experimental drugging and polypharmacy, which are now so rife in the profession.

If we are not mistaken, however, it is not the increased importance given to the nervous system in our studies of disease that has been the chief reason for the creation of these chairs of mental medicine. The new professorships are rather the fruit of an increased interest in the subject of insanity, as a disease for study and treatment. Now, we believe this interest to be in great part factitious, and unpromising of useful results to science or to the public.

It need scarcely be said how exceedingly vague is the use of the term insanity in popular language, or that it has hardly any more determinate sense in general literature. A single conception, that of a loss, more or less complete, of freedom of the will, makes up almost the entire idea of insanity, both in ignorant and in cultivated minds. It is curious to remark, by the way, how little this universal notion will bear to be examined. Surely, it is by the manifest freedom of his will, from known laws of thought and feeling, that we judge a man to be not sane, but insane. And on the other hand, a man is deemed sane not at all because his will appears self-determined, but because it is plainly governed by motives arising in accordance with fixed laws of the human mind.

The true legal idea of insanity is, no doubt, that of a certain degree of disorder or inability of the knowing faculties, determined in each case by long-established rules of law. But, in fact, the insanity of our courts is no less indefinite and illusive than that of popular language. We need only refer to the cases of Sickles, Huntington, Mary Harris, Cole, and McFarland, to prove that, in the legal medicine of to-day, insanity is too generally a fiction of the counsel and the experts, by which a jury may return the verdict "served him right," under the euphemism of "not guilty."

But what is the meaning of insanity in medicine? The greatest fallacies have, purposely or ignorantly, been offered in answer to this question. It is common to insist, at the outset, that the criterion of insanity is disease. But this is a futile attempt to substitute a positive for a negative conception. However much we may be accustomed to think of disease as a

mysterious but real entity, the word means nothing more than disorder. Again, great stress is laid upon the classification of insanity as "a form" of disease. But this is merely conventional, and has no warrant in medical philosophy. A proper form of disease must include a definite series of symptoms appearing either together or in a certain order. Insanity, however, is only a single symptom, and is not, in a strict sense, a symptom at all. Furthermore, it has been declared to be a fundamental doctrine in medical science that insanity is a bodily disease. Now, to say that mental disease is bodily disease is clearly absurd. Whatever may be possible in abstract thought, the distinction in terms between body and mind cannot be dropped for a moment. But the truth is, that in every formal treatise on insanity the mental manifestations are alone included in the definition. One bodily symptom, fever, is sometimes referred to in defining the disorder, but only to require that it shall *not* appear. We may notice that Griesinger, the latest authority, defines it concisely as "chronic delirium."

Of this technical insanity, it is admitted that its causes are in the last degree complex and remote. Its pathology must, of course, always remain a mystery until we can explain the physiological connection of mind and brain. Its therapeutics is confessedly almost a blank. Medically to "minister to a mind diseased" is still an undiscovered art. We are told, indeed, in the reports of our insane asylums, that insanity is very curable in its acute stages. But in the mass of its subjects no acute stage has ever been present. It has been chronic in its invasion as in its duration. This is, in fact, characteristic of the disorder, as its definition of "chronic delirium" implies. Most of the so-called cures of insanity are in cases of temporary delirium, from fevers, alcoholism, or some other form of blood poisoning, or else are only the intermissions between successive paroxysms. That insanity is really among the least curable of disorders we have only too abundant proof. Of the 25,000 insane in England, 90 per cent. are declared to be without even the hope of recovery; and there is reason to believe that the proportion of incurables is nearly the same in all countries.

But we ought never to lose sight of the fact that, after all, insanity is a purely abstract term, and in no wise represents a conception of natural science. Nothing can be more unwarranted than the use made by psychologists of scientific methods in their inquiries, and the assumption of scientific positiveness for their conclusions. It would not be easy to point to anything more entirely fallacious than, for example, the carefully-elaborated statistics of insanity which fill the pages of many asylum-reports. And one should also remember that insanity is no more a fact of logical demonstration than of scientific observation. It is not an inference which may be derived from given premises by logical steps, but a judgment reached by the mind instinctively, and without conscious reasoning. These considerations explain why both the most accurate observers and the acutest reasoners are so generally at fault in giving an account of their opinions respecting insanity before the courts. The fact is, that insanity is of far greater import as a practical problem of social life than as a scientific, a metaphysical, or even a medical question.

In conclusion, it is not strange that a subject which has been so overlaid with unmeaning facts and false reasoning should be uninteresting, and even unintelligible, to medical students. The lectures upon psychology, which have been begun at various medical schools in Great Britain and on the continent, have nearly all been soon discontinued. We would suggest that the entire field of pure mental disorder, beyond the limit of simple delirium, may well be left in this country to the study of minds specially constituted, and for other hours than the few which are given to the preparation for a general practice. Meanwhile, let us not forget to recommend the attentive study of nervous diseases to every advanced student. They promise to be the source of the most brilliant triumphs which await medical science and art in the immediate future.

T.

New York, Oct. 1870.

VERATRUM VIRIDE IN PUERPERAL CONVULSIONS.

To the Editor of the Medical Record.

Sir—In reading the proceedings of the New York Pathological Society, I was much pleased to see that the use of the veratrum viride in puerperal convulsions was meeting with much favor. For the past five years I have used it in many cases with better results than from any other course which I had heretofore pursued.

But a few weeks ago I used it (not in such doses as were reported by Dr. Finnell to have been given by a homœopathist) in a case of eclampsia, where the consulting physician and myself could distinctly count the pulsations at one hundred and seventy per minute, and where no amelioration of symptoms could be obtained with the use of chloroform and the other ordinary remedies in use for this grave malady. I gave Squibb's Fluid Extract, beginning with five drops, and increasing the dose one drop once in two hours until a decided impression was made upon the heart's action. Seven drops at that interval were all that was required to sufficiently diminish the pulsations to bring about the desired result. Also I wish to say a word relative to the use of the same remedy in pneumonia.

For eight years past I can truly say that, with the exception of an occasional Dover's powder, I have quite exclusively relied upon the veratrum in the treatment of this disease.

Within the past year I have substituted the chloral hydrate for the Dover's powder, and find it answers a better purpose.

D. Colvin, M.D.

Clyde, N. Y., January, 1871.

Medical Items and News.

Medical Science in Paris during the Siege.—Dr. J. A. Fort, writing from Paris to Professor Pacini, of Florence, says that the Surgical Society attempted to resume its weekly meetings on November 7th. Seven members only were present. M. Boinet spoke of some cases of tetanus which he had observed among the wounded in the Palace de l'Industrie; he attributed the disease to cold—the wards being badly warmed. M. Giraldès had also seen some cases of tetanus in the Val-de-Grâce Hospital. Both these surgeons spoke in praise of chloral, the use of which had been followed by recovery in two-thirds of the cases. The amount given varied from eight to ten grammes in twenty-four hours; it was dissolved in simple syrup, and given in doses of a spoonful. The Academies of Medicine and of Science were also meeting, and were occupied in discussing the existing state of affairs. The session of the School of Medicine had commenced, and the professors had begun their lectures. Dr. Fort had commenced giving a course of surgical anatomy.

REMOVAL OF THE TONGUE.—Mr. MacGillivray, surgeon to the Bendigo Hospital, reports, in the *Australian Medical Journal* for October, 1870, the successful removal of the whole tongue for epithelioma.

DR. GEO. M. BEARD has been appointed Electro-Therapeutist to the Demilt Dispensary. The Trustees of that Institution have created a separate department of Electro-Therapeutics, and have supplied it with all the apparatus necessary for the treatment of medical or surgical diseases by electricity.

This is the first regular appointment of the kind in any large public institution in this country.

SKIN DISEASES IN VIENNA.—Professor Hebra states that from 1850 to 1860, 227,000 patients were admitted into the General Hospital of Vienna; out of these, 30,000 were cases of skin disease.

DR. WILLIAM B. BIBBINS, M.D., of this city, died of typhoid fever, Jan. 19, aged 47.

RESOLUTIONS ON THE DEATH OF DR. BIBBINS. — At an adjourned Stated Meeting of the New York Medico-Historical Society, held Saturday evening, January 21, 1871, the following resolutions were unanimously adopted:—

Resolved, That in the decease of our President, William Burr Bibbins, M.D., this Society, together with the Medical Profession, to whom he was widely known here and throughout the country, has sustained a loss which it will be difficult for time to repair.

Resolved, That his uncompromising integrity of character, sincere devotion to duty, unquestioning acceptance of responsibility, and unwavering charity for his associates, distinguished Dr. Bibbins in and out of the profession; and, with his cultivated intellect, correct judgment, and singleness of purpose, contributed largely to secure such confidence of the profession in the efforts of the Medico-Historical Society as has rewarded their labors in past years.

Resolved, That Dr. Bibbins was one whose pure and upright life, and matured convictions, inspired confidence in whatever he did and said, and commanded respect among all with whom he was associated; and that, inscribed on the tablet of memory, the words "Integer vitæ" convey in his case a meaning seldom exemplified.

Resolved, That in the faithful discharge of his duties to the sick, in his enthusiastic devotion to the advancement of medical science, and in his labors in benevolent and charitable associations, the example of Dr. Bibbins should be held in lasting remembrance, as that of a man who, as far as may be possible to the human and therefore erring, regulated his conduct to his fellows by a desire to do to others as he would that they should do to him.

Resolved, That a copy of these resolutions, signed by the officers of the Society, be sent to the family of the deceased, and to the medical journals published in this city.

A. E. M. PURDY, M.D.,
Vice-President.

JOHN GORDON FRAZER, M.D.,
Secretary.

At a joint and special meeting of the Medical Society of the County of New York, and of the New York Academy of Medicine, held in the Lecture Room of the Madison Square Presbyterian Church—Rev. Wm. Adams, D.D.— Jan. 19, 1871, Dr. Gouverneur M. Smith, Dr. Edmund R. Peaslee, and Dr. Abram Jacobi, were appointed a committee to prepare resolutions expressive of the feeling of these societies in relation to the decease of Dr. William B. Bibbins. The meeting then adjourned to attend the funeral in the adjoining church.

Whereas, an All-wise Providence has removed by death William B. Bibbins, M.D.;

Resolved, That in the decease of Dr. Bibbins, the members of the Medical Society of the County of New York, and the Fellows of the New York Academy of Medicine, are called upon to mourn the loss of one of their number who has been endeared to them by his devotion to the interests of the medical profession; by his efficiency as a Treasurer, as a Trustee, and in other offices; and by his conscientious discharge of duty, as clearly but modestly evinced in the Christian principle which guided his public and private life.

Resolved, That while thus recognizing his professional and executive ability and rectitude, his late associates also bear witness that he possessed those traits of character essentially designating a genial companion, a true friend.

Resolved, That in his varied and ardent labors to promote the welfare of the poor of this metropolis, he has left an example worthy of emulation and worthy of public recognition.

Resolved, That a copy of these resolutions be preserved in the archives of the societies; and also that a copy, signed by the President and Secretary of the joint meeting, be transmitted to his family, and published in the medical journals.

HENRY D. BULKLEY, M.D.,
Chairman.

DISTRICT MEDICAL SOCIETY OF CO. OF HUDSON (N. J.).—At the annual meeting of this Society, held December last, the following officers were elected for ensuing year:—*President*, Dr. B. A. Watson, Jersey City; *Vice-President*, David Benson, Hoboken; *Secretary*, J. H. Comfort, Hudson City; *Treasurer*, T. F. Morris, Jersey City; *Reporter*, S. R. Forman, Bergen.

NEW YORK ACADEMY OF MEDICINE.—The following officers were elected for the ensuing year:—*President*, Dr. Edmund R. Peaslee; *Vice-President*, Dr. Austin Flint, Sr.; *Recording Secretary*, Dr. W. T. White; *Corresponding Secretary*, Dr. John G. Adams; *Treasurer*, Dr. James O. Pond; *Trustee*, Dr. Alfred Underhill; *Committee on Admissions*, Dr. John H. Hinton; *Committee on Medical Ethics*, Dr. Gouverneur M. Smith; *Committee on Medical Education*, Dr. Alonzo Clark. Dr. Samuel Blume was elected by ballot a Resident Fellow. The President appointed Dr. Alfred C. Post as the biographer of the late Galen Carter, M.D.

NEW YORK PATHOLOGICAL SOCIETY.—The following officers have been elected for the ensuing year:—*President*, A. L. Loomis, M.D.; *Vice-President*, H. D. Noyes, M.D.; *Secretary*, Dr. George F. Shrady; *Treasurer*, Dr. John H. Hinton.

GUN-COTTON.—It is not generally known that the best method for making gun-cotton was invented by Dr. William H. Ellet, at one time Prof. of Chemistry in Columbia College, New York, and afterwards in the South Carolina College.

DR. R. J. O'SULLIVAN has been elected Consulting Physician to the Department of Diseases of the Chest of the Eastern Dispensary of this city. This office was created for him as a reward for twelve years of continuous services to the institution.

A DELAY IN THE APPEARANCE OF OUR NEXT NUMBER may be possible, in consequence of the time required to get the report of the State Medical Society prepared.

Medical Society of the State of New York.

SIXTY-FIFTH ANNIVERSARY.

First Day—Morning Session.

The Society met at 11 A.M. on Tuesday, February 7, 1871, in the Supervisors' Room, Albany.

The meeting was called to order by the President, Dr. S. Oakley Vanderpoel, of Albany, and the Rev. Dr. Clark opened with an appropriate prayer; after which the President delivered his inaugural address.

THE PRESIDENT'S INAUGURAL ADDRESS.

After speaking of the benefits of medical associations to the physician, he referred to the good influences which the regular publication of reports of societies had upon these bodies in particular and the profession at large. He recommended the repeal of the usage in regard to the non-publication of papers in medical journals before their appearance in the Transactions; also, the continuance of the work of medical registration; the cultivation of the study of mental diseases in the colleges; and the proper recognition by the society of the useful labors of gentlemen connected with the Surgeon-General's office; concluding with touching tributes to the memories of Sir J. Y. Simpson, of Edinburgh, an honorary member, and Drs. W. B. Bibbins, Geo. T. Elliot, and other members who had died during the past year.

MISCELLANEOUS BUSINESS.

Dr. Didama moved that the several subjects alluded to in the President's address be referred to appropriate committees.

The President announced the following committees:—

On Credentials—Drs. A. N. Bell, J. G. Govan, H. McNutt.

On Arrangements—Drs. Quackenbush, W. H. Bailey, J. V. Kendall.

On Business—Drs. W. C. Wey, A. Underhill, H. B. Whiton.

On Obituary Notices—Dr. Platt Williams, by Dr. Thos. Hun; J. H. Reynolds, by Dr. R. L. Allen; Charles Barrows, by J. C. Hutchinson; Edward Hall, by Dr. Cummings; W. B. Bibbins, by Dr. Ellsworth Eliot; George T. Elliot, by Fordyce Barker.

Dr. J. V. Cobb offered the following resolution:

Resolved, That the President appoint a Committee of three to extend an invitation to the Governor, and to such members of the Legislature as belong to the medical profession, to attend the meetings of the Society during its Session.

Drs. Cobb, Gray, and Bozeman were appointed on such Committee.

Committee on publication of papers, as suggested by the President—Drs. Hutchinson, Bacon, and Orton.

Committee on Psychology—Drs. Gray, Hyde, and Banks.

Committee on Microscopic labors in the office of the Surgeon-General—Drs. E. R. Hun, McFarlane, and Ward.

Dr. Burr offered the following:

Resolved, That the Committee on Credentials be and it is hereby directed to transcribe from the Register of this Society, the names of all Permanent Members and Delegates from County Societies, which may from time to time, during the sessions of this Society, be entered therein, as fast as such names shall be registered, for the use of the Secretary in calling the Ayes and Nays, or in taking any other vote which the Society may direct.

Carried.

THE PRESENTATION OF PAPERS.

Dr. Burr also read a paper entitled, "Laceration of Perinæum and Bladder, with introduction of pieces of wood, formation of calculi, and operation."

Dr. Sayre read a paper entitled, "Two cases of Luxation of the Elbow backward."

Dr. Quackenbush introduced Dr. McIlvaine and Dr. Reid of Ohio.

PUERPERAL ECLAMPSIA.

Dr. Jewett read a paper entitled, "Puerperal Convulsions." He took the ground that the eclampsia was caused by the presence of a certain poison in the blood which acted differently on different temperaments, and that the only remedy seemed to be to get rid of the same through the natural emunctories as quickly as possible. The bowels, being the most available, were generally preferred.

Dr. Quackenbush, in remarking on the paper, stated that the really grave cases of eclampsia were those in which labor had not fairly commenced when the attacks occurred. He did not think purges in this condition of things would avail much.

Dr. Jewett stated that in a rigid and contracted os he should, all other things being equal, abstract blood.

Dr. Kneeland believed that chloroform was the remedy in such cases,—an opinion concurred in by Dr. Quackenbush and other members.

Drs. Frazier and Sherman remarked upon the paper, detailing their experiences.

The following members were invited to seats: Drs. F. A. B. Lewis, Watertown; L. Griffin, Binghampton; R. H. Ward, Troy; G. H. Hubbard, Lansingburgh; J. L. La Moree, Grahamville; J. C. Herrick, Saratoga Co.; J. G. Porteus, Warren Co.; G. D. Van Vranken, Saratoga Co.; J. G. Johnson, Saratoga Co.; C. A. Robertson, Albany; E. M. Carmichael, Renn. Co.; W. B. Morgan, Albany; Walter Booth, Onondaga Co.; Stephen R. Millington; Henry March, Albany; Henry Lanning, Tompkins Co.

Dr. Granger, of Lawrenceville, Tioga Co., Penn., was introduced to the Society.

The Society then adjourned, to meet at Association Hall, at 3 p. m.

First Day.—Afternoon Session.

The Society met, pursuant to adjournment, in the Lecture Room of the Young Men's Christian Association, and was called to order by the President, Dr. Vanderpoel.

It was resolved to postpone the reading of the minutes till the morning of each day.

The President announced the following Nominating Committee:

District 1. J. G. Adams.
" 2. R. Loughran.
" 3. J. R. Boulware.
" 4. Francis Burdick.
" 5. Jno. P. Gray.
" 6. H. K. Bellows.
" 7. H. D. Didama.
" 8. J. F. Rochester.

PERMANENT MEMBERS FROM DIFFERENT DISTRICTS.

Concerning Permanent Members not from their own districts, Dr. Orton presented the following communication from the Broome Co. Medical Society:

"The following resolution was unanimously adopted at the Annual Meeting of the Broome Co. Medical Society, held in the City of Binghamton, Oct. 4, 1870:

Resolved, That, in the judgment of this Society, the annual election by the State Society of permanent members for the

several Senatorial Districts, is exclusively due to those physicians eligible, who are residents of the districts for which such election is made; and that to elect as permanent member of the State Society for one district, any person residing in another, is an infringement of the rights and privileges of those who are eligible for permanent membership in such district.

J. G. ORTON, *Secretary.*

On motion, laid on the table.

The Treasurer, DR. LANSING, read his Annual Report. Referred to Auditing Committee, composed of Drs. Sherman, Sanders, and Doolittle.

PRIZE ESSAYS.

DR. ROCHESTER, Chairman of Committee on Prize Essays, reported that the *Merritt H. Cash* prize was awarded to Dr. S. Fleet Speir, of Brooklyn, for a paper entitled, "A new method of arresting Surgical Hemorrhage by the Artery Constrictor."

The Corliss Prize Essay was awarded to Dr. Ghislani Durant, of New York.

DR. BAILEY, the Secretary, moved, that hereafter the names of the Presidents be printed in a separate column; and stated that as the result of his examinations he had found that this meeting should be the sixty-fifth instead of the sixty-fourth.

A CHARGE OF PLAGIARISM.

DR. SQUIBB presented the following preamble and resolutions:

Whereas, There appears in the published transactions of this Society for the year 1868, at page 142, *et seq.*, an article entitled, "Effects of the Meteorological Influences on Health, by Wm. Faulds Thoms, M.D., Surgeon to the Howard Hospital, Physician to the New York Dispensary, Surgeon to the Eastern Dispensary, etc." And

Whereas, This article is in large part copied word for word from Parkes's *Manual of Practical Hygiene*, 2d Eng. Ed., commencing at page 430, without credit given or marks of quotation used, and is therefore a plagiarism. Be it

Resolved, That this Society owes it to Dr. Parkes of London, as well as to itself, to apologize for their appropriation of his labor and language without credit.

Resolved, That a copy of this preamble and resolutions, authenticated by the signatures of the President and Secretary of the Society, be sent to Dr. Parkes of London.

Adopted.

URETHROCELE, CATARRH, AND ULCERATION OF FEMALE BLADDER.

DR. BOZEMAN, New York, read a paper entitled, Urethrocele, Catarrh, and Ulceration of the Female Bladder. He considered these several diseases from a common stand-point, regarding them as so many aspects of the same malady. He showed by the citation of typical cases that it is impossible, from the long chain of morbid results, for the shrewdest diagnostician to say where the disease of one structure ends and that of another begins.

Urethrocele, first pointed out by Sir Charles Mansfield Clarke in 1814, he said, had been almost completely overlooked from that time to the present moment by authors who have written special treatises on the diseases of women, both in this country and in Europe.

As causes of this disease, he enumerated mechanical violence from long pressure of the child's head in the inferior straits, and from the maladroit use of instruments in effecting delivery. Disproportion of the size of the male organ to that of the vagina, and too frequent coitus. Urethritis, whether of traumatic, gonorrhœal, or catarrhal origin, resulting in the formation of organic stricture as in the male. The last-named cause he considered extremely rare.

The "order of morbid changes" he regarded as follows: Eccentric hypertrophy of the muscular structure of the urethra—thickening of the walls with dilatation of its calibre. This results (from the unyielding triangular ligament in front) in distortion of the urethral canal and coarctation of its sides, from which there is no obstruction offered to the passage of a large elastic catheter with proper curve at any stage of the disease. Here the stream of urine encounters its first obstruction, when the force of the column in its passage is expended upon the walls of the urethra in the upper part of its course. The effect of this is further dilatation from mechanical pressure, resulting finally in the formation of a urinous tumor which carries down before it the adjacent vaginal wall, as usually seen between the nymphæ, filling up the ostium vaginæ. This tumor he calls urethrocele in contradistinction to cystocele, with which it is very often confounded.

The sequences of this primitive disease observe very much the same order as those seen in the male from stricture. First, retention and decomposition of the urine (only a few drops at first); irritation and congestion of the mucous lining, extending into the bladder under the influence of exacerbative causes; chronic cystitis; and finally, ulceration, when all the aspects of the morbid process from beginning to end are blended into one common malady.

The *treatment* is based upon surgical resources alone, as it is supposed that the disease has advanced to its several critical stages, and that the ordinary therapeutical appliances no longer promise permanent relief. For the urethrocele just before it merges into persistent vesical catarrh, tapping of the urethra through the vaginal wall at the most dependent point of the tumor is the procedure proposed. This gives a free outlet to the urine; and the hypertrophied urethra, being thus placed at rest, returns to its normal size and direction, in accordance with well-known physiological laws. When a healthy condition of the parts is re-established, the artificial aperture is closed up with the button suture. Should there be at the time of this operation a redundancy of tissue, either in the vagina or urethra, it is to be retrenched, the object in all cases being to straighten the urethra in its entire course and give to the urine a free and uninterrupted outlet.

When the urethrocele has become complicated with confirmed vesical catarrh and hypertrophy of the coats of the bladder, then an opening into the latter through the vesico-vaginal septum is required. The aperture here should be large, the size of a half dollar, and remain open until the general health is restored, and the urethra and bladder return to their normal anatomical characters.

The ulceration of the mucous coat of the bladder, the third evidence of the malady, is treated in the same way as last described, excepting that the aperture should be much larger and be kept open longer.

In the case of ulceration cited, Dr. Bozeman says three-fourths of the membrane had been destroyed at the time he cut into the bladder. The surface of the muscular coat, as far as the morbid process had extended, was completely bare; no dissection by the knife of the anatomist could have been more perfect. The treatment was concluded after fourteen months, the patient having been discharged cured in April, 1862.

Dr. N. G. Davis, of Greenwood, Miss., in a letter to Dr. Bozeman, dated January 18th, 1871, says, that the case had been under his observation ever since the operation was performed, and the cure remains perfect. The woman can go as long without having to empty the bladder as any one, and experiences no inconvenience in the passage of the urine.

This cure, Dr. Bozeman believes to be the only one on record after such extensive destruction of the tissue. He attributes to Prof. Willard Parker, of New York, the credit of having first proposed and practised cystotomy for the relief of catarrh of the male bladder, and from the encouragement thus given, he was led to apply the same principle of treatment to the female bladder.

The following were appointed the Committee on Ethics:—Drs. Orton, Dean, Doolittle.

The Business Committee read the following papers by title:—"Biographical Sketch of the late Dr. Thomas Cock," by Gurdon Buck, M.D.; "On Trismus Nascentium," by Dr. James S. Bailey, of Albany, N. Y.

The President announced the name of Dr. F. B. Hough, from Lewis County, to fill the vacancy in the Committee on Registration caused by the death of Dr. Brinsmade, of Troy, N. Y.

PERMANENT MEMBERS FROM DIFFERENT DISTRICTS.

To the Medical Society of the State of New York:

The undersigned members of the medical profession residing in the Fifth Senatorial District, respectfully represent that, as appears by the published volumes of the Transactions of the Society, they have been made eligible for election as permanent members of said Society; that said eligibility with many of the undersigned has existed for several years, and that the honor of an election as permanent member of the State Society is, by the Constitution and By-Laws of said Society, justly their due.

The undersigned have learned with surprise that at the last annual meeting of the State Society their claims were passed over, and a gentleman from another district was elected as one of the two entitled to an election from the Fifth Senatorial District, and that the person thus elected was a resident of the city of Albany.

The undersigned respectfully protest against such an unjust proceeding, claiming that the yearly selection for permanent members of the Society for the several districts should be made from the residents of said district who have been made eligible, and that to pass them by, and to give the election to a non-resident, is, in their judgment, a disregard of their privileges, and a violation of the Constitution and By-Laws of the Society; against which the undersigned respectfully remonstrate.

	County.	When made eligible.
G. L. Halsey	Otsego	1866.
T. B. Smith	Otsego	1867.
J. K. Leaning	Otsego	1868.
Horace Lathrop	Otsego	1870.
G. W. Cooke	Otsego	1870.
Frank D. Beebe	Madison	1867.

September, 1870.

The following was also received:—

CLINTON COUNTY MEDICAL SOCIETY,
PLATTSBURG, N. Y., January 10, 1871.

At the Annual Meeting the following resolutions were unanimously adopted:

Whereas the Members of the Clinton County Medical Society did recommend Arthur S. Wolff, M.D., Physician of the Clinton State Prison, our late Delegate to the State Medical Society, for permanent member; and whereas the Society did not act on their recommendation, but, on the contrary, have elected William H. Graig, of Albany, who is located in the Third District, and not in the Fourth; therefore, be it unanimously

Resolved, That we again recommend Arthur S. Wolff, M.D., as a fit and proper person, professionally and socially, to become a permanent member of the State Medical Society. In addition to our claims, being one of the oldest county societies in the State, we have no permanent member. Arthur S. Wolff, M.D., is the oldest eligible member in the Fourth District. His election would be gratifying to every member of our society. And be it further

Resolved, That our delegate be instructed to urge our claims in favor of Arthur S. Wolff, M.D., and that a copy of these resolutions be transmitted to the President of the State Medical Society and Nominating Committee.

A. C. BUTLER,
Pres. of Clinton Co. Med. Soc.

DR. JOHN P. GRAY read a paper "On the Relations of Insanity to Physical Diseases."

Remarks were made upon the paper by Dr. E. H. Parker.

The Society then adjourned to meet at 8 o'clock.

FIRST DAY—EVENING SESSION.

The Society met, agreeably to adjournment, at 8 o'clock, at Association Hall. The President, Dr. Vanderpoel, called the meeting to order.

ASTIGMATISM AND OTHER DEFECTS OF SIGHT FROM ABNORMAL REFRACTION.

DR. H. D. NOYES, of New York, delivered a lecture on astigmatism, illustrated by the magic lantern. After first describing the ordinary phenomena of vision by models and lenses, he showed the departures from the normal functions constituting astigmatism, and illustrated very satisfactorily the manner in which the different cylindrical glasses corrected these defects.

The meeting then adjourned to meet at 9 o'clock on Wednesday morning.

SECOND DAY—MORNING SESSION.

The Society was called to order by the President, and prayer was offered by the Rev. Dr. Halley. The minutes of the day preceding were read and approved.

DR. QUACKENBUSH proposed several gentlemen as members by invitation.

ANOTHER PROTEST FROM THE COUNTRY MEMBERS.

DR. E. H. PARKER presented a resolution, on behalf of the Dutchess County Medical Society, protesting against the appointment of permanent members from districts to which they may not belong. It was referred to the Nominating Committee.

REPORTS OF DELEGATES.

The following gentlemen presented their reports as delegates to sister societies: Dr. Sherman, for the Vermont State Medical Society; Dr. Hart, for the Maine State Medical Society; and Dr. Corliss from the Massachusetts and Rhode Island State Medical Societies respectively; and Dr. Bradford from the Ohio State Medical Society.

DR. KNEELAND called for a reconsideration of the resolution of Dr. Squibb, with reference to the paper in the Transactions of 1868 by Dr. Thoms. After some discussion it was, on motion, referred to the Committee on Ethics.

THE PROTECTION OF FOUNDLINGS.

DR. JACOBI, New York, presented the following, which were adopted:—

Whereas, Humanity acknowledges the claims of every human being to life and some degree of prosperity, and recognizes, in every civilized country, the

right of every newborn to be protected and supported; and

Whereas, Political economy requires the saving of a being which has given rise to outlay until and after it can become useful and repay the expenses incurred in its full development; and

Whereas, The moral constitution of society requires that every member of society should obtain a sufficient training of its intellectual and moral powers; and

Whereas, The mortality of infants, being large from natural causes, is three times larger in public institutions destined for the maintaining of infants than in the general infant population; and

Whereas, The Board of Commissioners of Charities and Correction, always willing to be guided by competent advice, and desirous of doing their best, have *already* had a report prepared for them suggesting changes and improvements in the raising of their infants;

Therefore, it is resolved by the State Medical Society to appoint a committee to investigate, and report in the meeting of 1872, upon the following subjects:—

1st. The causes of the fearful mortality of abandoned infants in general, and those in large public institutions in particular.

2d. The reasons for the giving up of large institutions, and the successes of the dispersing system for abandoned infants, in every country of Europe, where the preservation of lives was an object.

3d. The causes of the unusually large infant mortality in the institutions in charge of either public or self-constituted authorities in New York City and State.

4th. The plans and means for improving the condition of foundlings and abandoned children in New York City and State—

a. During their infancy, when they are most subject to disease and death—

b. During childhood and adolescence, when they require an education sufficient to make them useful members and prevent them from becoming enemies of and dangers to society.

The President appointed the following committee on Dr. Jacobi's resolutions of inquiry: Dr. Jacobi, New York; Dr. White, Buffalo; Dr. Dean, Rochester; Dr. Thos. Hun, Albany; Dr. Hutchinson, Brooklyn.

CONCERNING PERMANENT MEMBERS.

Dr. Sanders offered the following:—

Whereas, Dissatisfaction has arisen from the election of permanent members of this Society that were not residents of the districts entitled to their membership, therefore,

Resolved, That it is the sense of the Society that permanent members should and must, in all cases, be selected from such persons as are eligible residing in the districts entitled to such membership.

Adopted.

ON BY-LAWS.

Dr. O. White, Chairman of Committee on By-Laws, reports through the Secretary as follows:—

"The Standing Committee on By-Laws beg leave to report through the chairman of the committee, that during the past year the following County Medical Societies have submitted their Constitution and By-Laws to the committee for examination: St. Lawrence Co. Medical Society; Monroe Co. Medical Society; the Genesee Co. Medical Society; the Cattaraugus Co. Medical Society; and the Chatauqua Co. Medical Society."

Dr. R. Newman, New York, reported as delegate to the Connecticut Medical Society, and Dr. Shumway reported as delegate to the Vermont Medical Society.

Dr. Frank Hyde read a biographical sketch of the late Dr. Alex. Thompson.

Dr. D. B. St. John Roosa (New York) presented a statistical report of 494 additional cases of aural disease seen in private practice.

DIVERGENT SQUINT.

Dr. Agnew, of New York, gave a brief verbal abstract of a paper on the operations for divergent squint by advancing the faulty internal rectus, illustrating the same by blackboard diagrams, showing Mr. Critchett's method and his own. Dr. A. called attention to the fact that divergent squint frequently resulted from the common operation for convergent squint, and especially warned the members against the contemporaneous tenotomy of both internal recti, except in cases in which the dynamics of the faulty muscles had been carefully studied in conjunction with a proper determination of the refraction of both eyes. He also warned the members against attempting to cure divergent squint by tenotomy of the external recti alone.

Dr. H. D. Noyes offered some general remarks upon the subject, indorsing Dr. Agnew's views.

A NEW JOINTED SILVER CATHETER.

Dr. T. H. Squire, of Elmira, exhibited a jointed silver catheter for use in difficult cases of retention of urine, more particularly in such as are complicated with enlarged prostate. The jointed portion is confined to the curve, and is formed of a series of cups fitting into each other, and so arranged as to give a smooth and continuous surface externally. The cups or sections are held in position by a chain in the course of the curve, and a rod in the rigid portion, this rod terminating at the handle and fixed there by means of a screw bolt passing through a perforation.

Dr. Hutchinson, of Brooklyn, stated that he had made use of the instrument in several difficult cases, and was satisfied in view of the flexibility and yet firmness of the curve that it was superior to any in use.

His testimony was corroborated by Drs. Sayre, of New York, Wolcott, of Utica, and Corliss, of Greenwich. The last gentleman could not, however, see how a false passage could be avoided. Dr. Squire stated in answer that it was impossible to enter a false passage with it, and Dr. Corliss was pleased to know that such was the fact.

A FLEXIBLE SILVER BONE PROBE.

Dr. Sayre, of New York, in the same connection, presented a probe similarly constructed, which he had used with benefit in cases of necrosis in which the sinus was long and tortuous. He had never failed with this instrument to detect the presence of necrotic tissue in the difficult cases.

ANÆSTHESIA AND A NEW INSTRUMENT.

Dr. E. R. Squibb read a paper on anæsthesia, in which he described, among other things, his new instrument for the administration of ether unmixed with air.

Dr. Noyes followed with a description of an ether apparatus devised by him more especially for operations upon eye patients. It was composed of a framework of wire, bent to fit accurately over the nose, mouth, cheek, and chin, covered with rubber, and continuous with a tube communicating with a powder-flask arrangement containing the sponge, and communicating in its turn with an india-rubber bag.

Dr. Sayre stated that he had been in the habit of

administering chloroform, without the admixture of air, by means of an apparatus somewhat similar, but with a valve-like arrangement to allow of the exit of the expired air. A very small quantity of the anæsthetic was necessary by such means.

Dr. Sherman gave a detailed account of his experience with chloroform, which, however, contained nothing specially new.

The following papers were read by title and referred: Drs. Winston, "Biographical Sketch of Minturn Post, M.D.;" J. B. Smith, Nyack, "Obituary Notice of M. C. Hasbrouck;" C. C. F. Gay, Buffalo, "Radical Cure of Hernia," also "Ligature of Subclavian Artery for Aneurism;" P. O. Williams, "Fracture of one of the Bones of Spinal Column, with drawing."

ARTERY CONSTRICTOR.

Dr. S. Fleet Speir exhibited and described his artery constrictor, and presented specimens showing the effects of its action in restraining hemorrhage by the invagination of the internal and middle coats.

The Society then, on motion, adjourned to meet at 3 o'clock, P.M.

Second Day—Afternoon Session.

The Society reconvened at 3 P.M., and was called to order by Vice-President Dr. Dayton.

Dr. Thomas Addis Emmet, of New York, read a paper on "Prolapsus Uteri, its Cause and Treatment."

Dr. W. James, of Franklin, read a paper on "Veratrum Viride."

Dr. Hutchinson made his report on a portion of the President's address, recommending that the second sentence of paragraph 6, chap. 3, of the by-laws (page 70 of the Transactions of 1869) be replaced as follows:

"The author of any paper read before the Society may have the privilege of publishing the same in any legitimate medical publication, unless objected to by a vote of the Society; and any paper presented to the Society by title may be published by the author, unless objected to by the Committee on Publication," and that the words "or which has already appeared in any book or journal," in the third sentence of the same section and chapter, be stricken out. Accepted and adopted.

THE CASE OF DR. THOMAS.

Dr. H. W. Dean, Chairman of the Committee on Ethics, reported as follows:

"The Committee on Ethics, to whom was referred the case of Dr. Thoms, whose case was brought before the Society yesterday, after hearing the statements of Dr. Thoms, recommend that he be permitted to make a statement of facts before the Society, from which more satisfactory results may be obtained than by definite action of this Committee.

"In relation to the difficulty connected with the Niagara County Medical Society, the committee respectfully report that, after examining all the facts brought to its knowledge, its action is embarrassed by the existence of questions for the solution of which no precedent appears in the history of the Medical Societies in this State to guide its actions. For a score of years or more, the testimony elicited shows that the Niagara County Medical Society has comprised elements that should have placed it beyond the fellowship of this Society; a large number of its members have been in constant and open violation of not only the spirit of our code, but also the express rules of order and professional conduct enjoined by this Society.

"The committee find that for two or three years past a minority membership of the Society has made laudable efforts to correct the evils alluded to, but that any question tending to the discipline of its members could not be entertained, by reason of the majority influence against such action. A minority membership, alleging its inability to effect such reformation among its members as to make effective the code of ethics governing this Society, did, at a semi-annual meeting of the Niagara County Medical Society, held in June last, by resolution dissolve said Society and organize a new Society.

"The Committee are of the opinion that a County Medical Society in this State is not competent to the work of its own dissolution, but very respectfully submit the question to the State Medical Society. At the same time the Committee desire to express the hope that the seceding portion of the Niagara Medical Society may be advised to such action as will secure to them the privilege and relationship of the most rigidly governed Societies.

"If the Committee rightly estimate the privileges of the County Medical Societies, the resources of the minority membership of the Niagara County Medical Society are to the statutes of the State now existing or to special legislation.

J. G. Aston,
A. F. Doolittle,
H. W. Dean,
Committee."

That part of the report relating to Dr. Thoms was fully discussed, and finally the preamble and resolutions of Dr. Squibb, presented Tuesday, charging him with plagiarism, were unanimously adopted.

That part of the report relating to the Niagara County Medical Society, after much discussion, was referred back to the Committee.

DR. SAYRE AND HIS MALPRACTICE SUIT.

Dr. Dean, from the Committee on Ethics, presented the following, which was unanimously adopted:—

"Whereas, An action for alleged malpractice was recently brought against Lewis A. Sayre, M.D., of the city of New York, a permanent member of this Society, in which he was maliciously and falsely accused, and which resulted in a triumphant vindication of his professional skill by an award of damages in his favor; and

"Whereas, By fearlessly meeting this groundless prosecution, in resisting all attempts at proffered compromise, and by vigorously forcing this scandalous suit to a trial, he secured a judicial decision which established a legal principle of great value to the whole medical profession, and which has been justly characterized as 'one of the greatest advances in jurisprudence during half a century, and will do much to prevent malicious attacks upon medical men;' therefore,

"Resolved, That, in the opinion of this Society, the services rendered our common profession by Dr. Lewis A. Sayre, by his successful effort to protect its honor and interests, merit a distinct recognition, and that a unanimous vote of thanks is hereby tendered him."

Dr. Samuel Peters, of Cohoes, read a paper on "Spinal Irritation."

The Society then adjourned till evening, when the annual address was delivered by Dr. Vanderpoel.

Second Day—Evening Session.

The Society convened at 8 P.M., when the President, Dr. S. Oakley Vanderpoel, gave a very interesting, elaborate, and learned address upon "The different Relations of Pathology to the Study and Progress of Medicine." It was listened to with marked attention by a large and appreciative audience, and was decidedly one of the best efforts of the kind with which the

Society has been favored for many a year. The Society were then sumptuously entertained by the President at his residence.

THIRD DAY—MORNING SESSION.

The Society met at 9 A.M., and after being called to order by the President, Dr. S. Oakley Vanderpoel, prayer was offered by the Rev. Dr. John Peddie.

On motion, the regular order of business was dispensed with for the purpose of presenting some of the papers left over from the last session.

DR. E. R. HUN, of Albany, read a paper "On Glosso-Pharyngeal Paralysis."

DR. JACOBI remarked upon the paper, giving a detailed account of the usual morbid appearances found in these affections, the one presented by Dr. Hun being, in respect to the hardening of the nerve-tissue, unusual.

DR. J. G. RICHARDSON, of Penn. Hosp., read, by invitation, a paper "On the Diagnosis of Early Pulmonary Phthisis by the Microscope," setting forth the value of recognition of the yellow elastic walls of the air vesicles.

COMMITTEE ON PSYCHOLOGY.

To the Medical Society of the State of New York:

The committee on that part of the President's inaugural address which refers to psychology, beg leave to report as follows:—

That they recommend the practical carrying out of the views of the President on the importance and imperative necessity of the investigation not only into morbid conditions found in the insane, but as well into those pathological states capable of ultimating in insanity.

The importance of this cannot be overestimated, and it is alike the duty of the general practitioners as well as those having charge of hospitals for the insane, to make the most careful clinical observations in every case coming under their care with the same scrutiny that is demanded and conceded in every form of neuroses. It is true, in the present state of psychological science, for the general practitioner, that the data for observations are defective; but it has been equally true, as applied to any wide field of medical research.

The foundation of psychological science must be laid in pathological facts, and these can only be obtained by large experience.

Therefore to clinical observations must be added post-mortem examinations.

To accomplish these results most efficiently it is absolutely necessary that students of medicine should include in their study of nervous diseases, insanity as well as other cerebral affections.

The committee therefore recommend the passage of the following resolutions:—

Resolved, That this society earnestly approves the views and recommendations of the President in making the study of insanity a necessary and inseparable part of the study and teaching of the neuroses.

Thorough instruction can only be accomplished by the means of clinical and didactic instruction, and that this step is alike due from every medical school to the standard of medicine at the present time as well as to medical science itself.

Resolved, That every medical college be requested to carry these suggestions into practical application, and that the Secretary of the State Medical Society be directed to transmit a copy of these resolutions to the several medical colleges of the State.

JOHN P. GRAY,
JAMES L. BANKS.

Accepted and adopted.

DR. PARKER presented the following:—

Resolved, That the Secretary be instructed to have three hundred extra copies of the proceedings of each annual meeting printed in a separate form and ready for distribution at the next succeeding annual meeting, for the use of the members present.

Carried.

DR. WHEELER, on vaccination, offered the following:—

Resolved, That the Medical Society of the State of New York recommend the passage of a law requiring previous vaccination as a condition of admission of pupils to the public schools of the State, and that the President appoint a committee of three members to present the subject to the consideration of the Legislature.

ON THE WORK AT SURGEON-GENERAL'S OFFICE.

The Medical Society of the State of New York, desirous of expressing its interest in, and appreciation of, the work of the Microscopical Department of the United States Army Medical Museum:—

Resolves, That the investigations of this department, particularly in the study of healthy and diseased human tissues by means of high powers of the microscope and of photo-micrography, and the dissemination of results by means of photography, have materially added, and still promise to add, to the world's knowledge of health and disease, and to the world's facilities for relieving disease and averting death;

That, for a long time to come, at least, these results would not be attained without the opportunities furnished at the Army Medical Museum;

That the wise liberality of the Government in carrying on this work is heartily appreciated by the medical profession, and should be gratefully remembered by the citizens of this country.

That copies of these resolutions be sent to the Surgeon-General of the United States, and to Dr. J. J. Woodward of the U. S. A. Medical Museum at Washington.

EDWARD R. HUN,
R. H. WARD.

Unanimously adopted.

REPORT OF COMMITTEE ON NOMINATIONS.

The Committee on Nominations unanimously submit to the Society the following report:

For President.
DR. WILLIAM C. WEY, of Elmira.

For Vice-President.
DR. ANDREW F. DOOLITTLE, of Herkimer.

For Secretary.
DR. WILLIAM H. BAILEY, of Albany.

For Treasurer.
DR. CHARLES H. PORTER, of Albany.

For Censors.—Southern District.—Drs. Edward R. Squibb, of Brooklyn; Samuel T. Hubbard, of New York; N. C. Heusted, of New York. Eastern District.—Drs. B. P. Staats, of Albany; P. McNaughton, of Albany; C. C. Covell, of Kingston. Middle District.—Drs. M. M. Bagg, of Utica; Horace Lathrop, of Cooperstown; Charles G. Bacon, of Fulton, Oswego Co. Western District.—Drs. J. F. Miner, of Buffalo; C. C. Wyckoff, of Buffalo; D. Calvin, of Clyde.

For Committee on Correspondence.—1st district, Dr. Geo. F. Shrady, of New York; 2d district, Dr. Abraham Crispell, of Rondout; 3d district, Dr. Henry B. Whiton, of Troy; 4th district, Dr. R. L. Allen, of Saratoga; 5th district, Dr. W. T. Bassett, of Mount Vernon; 6th district, Dr. J. G. Orton, of Binghamton; 7th district, Dr. H. N. Eastman, of Geneva; 8th district, Dr. J. F. Miner, of Buffalo.

For Permanent Members.—1st district, Drs. Thomas Addis Emmett, of New York; S. Fleet Speir, of Brooklyn. 2d district, Drs. J. L. Lamoree, of Sullivan; R. Loughran, of Ulster. 3d district, Dr. Geo. H. Hubbard, of Lansingburg; Nelson Fanning, of Catskill. 4th district, Drs. Hiram McNutt, of Warren; B. F. Sher-

man, of Ogdensburg. 5th district, Drs. Frank S. Law, of Oswego; Walter Booth, of Booneville. 6th district, Drs. G. S. Halsey, of Otsego; S. F. McFarland, of Oxford. 7th district, Drs. Nathan R. Tefft, Onondaga Hill; Jas. W. Wilkie, of Auburn. 8th district, Drs. William Van Pelt, of Erie Co.; R. C. Reynolds, of Rochester.

Eligible for Permanent Membership.—1st district, Drs. G. S. Winston, of New York; D. B. St. John Roosa, of New York; A. E. M. Purdy, of New York. 2d district, Dr. Thomas Hammond, of Dutchess. 3d district, Drs. Matthew H. Benton, of Troy; Francis H. Parmelle, of Green Bush; Chs. L. Hubbell, of Troy; Eben. W. Carmichael, of Sand Lake; John P. Whitbeck, of West Troy; E. Whittlesy, of Greene. 4th district, Drs. Moses H. Colby, of Dean's Corners; Newton H. Ballou, of Mechanicsville; Alfred J. Long, of Whitehall. 5th district, Dr. H. G. P. Spencer, of Watertown. 6th district, Drs. William Bassett, of Binghamton; T. H. Squire, of Elmira; F. M. Perrine, of Lyonsville. 7th district, Dr. Roger W. Pease, of Syracuse. 8th district, Drs. Simon T. Clark, of Lockport; C. N. Palmer, of Niagara.

Honorary Members.—Drs. William H. Byford, of Chicago, Ill.; Edwin M. Snow, of Providence, R. I.; Wilmer Worthington, of West Chester, Pa.; William McCullom, of Woodstock, Vt.; John R. Webb, of Galveston, Texas; E. R. Hunt, of Hartford, Conn.

Eligible for Election for Honorary Members.—Drs. Greenville Dowell, of Galveston, Texas; J. H. Lore, of Laclare, N. J.; M. Nélaton, of Paris, France; Rudolph Virchow, of Berlin.

For Honorary Degree of Doctor of Medicine.—Dr. —— Odell, of Otsego Co.

Delegates to the American Medical Association.—Drs. E. S. F. Arnold, of Westchester; C. V. Barnett, of Greene; R. Loughran, of Ulster; Jacob Snell, of Montgomery; G. S. Winston, of New York; Alfred Underhill, of New York; L. A. Sayre, of New York; Samuel G. Woolcott, of Utica; Edwin Hutchingson, of Utica; E. H. Parker, of Poughkeepsie; Horace Lathrop, of Otsego; Geo. A. Dayton, of Otsego; E. T. Krackowitzer, of New York; E. L. Beadle, of Poughkeepsie; Henry D. Didama, of Syracuse; H. C. Hendrick, of Cortland; Nelson Niverson, of Schuyler; H. R. Bellows, of Norwich; G. S. Winston, of New York; E. R. Hun, of Albany; Lin. Moore, of Albany; Jno. P. White, of Buffalo; A. N. Bell, of Brooklyn; A. J. Long, of Whitehall.

Delegates to Massachusetts State Medical Society.—Drs. Oliver White, of New York; J. O. Van Hovenburgh, of Ulster; E. R. Hun, of Albany; John P. Gray, of Utica; J. C. Hutchinson, of Brooklyn; Wm. Govan, of Stony Point.

Delegates to Connecticut State Medical Society.—Drs. Hiram Corlies, of Washington; H. D. Bulkley, of New York; Frank Burdick, of Johnstown; J. Lindsley, of New York; C. C. Covell, of Ulster.

Delegates to New Jersey State Medical Society.—Drs. Ferris Jacobs, of Delhi; John R. Van Kleck, of New York; C. C. Covell, of Kingstown.

Delegates to New Hampshire State Medical Society.—Drs. Jas. V. Kendell, of Onondaga; M. R. Holbrook, of Poughkeepsie; L. B. Smith, of Rockland.

Delegates to Vermont State Medical Society.—Drs. L. Burton, of Montgomery; John B. Shaner, of Herkimer; Frank S. Low, of Oswego.

Delegates to Pennsylvania State Medical Society.—Drs. Marcus M. Wood, of Chenango Co.; E. W. Bottom, of Wayne; H. S. Chubbuck, of Elmira.

Delegates to Ohio State Medical Society.—Drs. A. Crispell, of Rondout; Gurdon Buck, of New York; Jacob Hunt, Utica.

Delegates to Maine State Medical Society.—Drs. S. Barrett, of Genesee; E. M. Alaba, of Onondaga; A. D. Hull, Rensselaer; E. S. F. Arnold, of Westchester.

Delegates to Rhode Island State Medical Society.—Drs. A. C. Hull, of Ulster; J. L. Banks, of New York; Samuel Hart, of Kings.

Delegates to the Illinois State Medical Society.—Drs. Derilo White, of Chenango; Geo. F. Shrady, of New York; J. C. Hutchinson, of Kings.

Committee on Statistics.—1st district, Drs. Ellsworth Eliot, of New York; 2d district, Geo. J. Fisher, of Sing Sing; 3d district, Chas. H. Porter, of Albany; 4th district, Alex. M. Vedder, of Schenectady; 5th district, A. S. Odell, of Brookfield, Mad. Co.; 6th district, John J. Orton, of Binghamton; 7th district, Nelson Niverson, of Hector, Schuyler Co.; 8th district, S. B. Coates, of Batavia.

Committee on Prize Essays.—Drs. Thomas S. Rochester, of Buffalo; Henry Dean, of Rochester; Sanford Eastman, of Buffalo.

Committee on Publication.—Drs. Thomas Hun, of Albany; J. V. P. Quackenbush, of Albany; W. H. Bailey, Albany.

Committee on By-Laws.—Drs. Oliver White, of New York; Thomas Hun, of Albany; W. H. Bailey, of Albany.

Respectfully submitted,
JOHN G. ADAMS, Chairman.

CONCERNING CARELESS PHARMACY, ETC.

Preamble and Resolutions offered by E. R. Squibb, M.D.:

Whereas, The Medical Society of the State of New York is informed of two measures that have been or will be brought before the Honorable Legislature of New York during the present session, for the purpose of protecting the people of the State against the rapidly increasing number of disasters which occur from incompetent and careless pharmacy.

And whereas the interests of this Society and of the people are the same upon this subject, because the utility of the profession which this Society represents to the people at large depends very much upon the quality of the medicines with which it is supplied, and the competency with which these are prepared for application. One of the measures proposed for protection is the appointment of a Board of Examiners to test the qualifications of those who shall be allowed to dispense medicines.

The other is to supply means to assist a chartered institution to extend its design for educating pharmacists.

All legislative bodies in this country show a strong indisposition to interfere with free trade, even in so vital a matter as medicine; and the practical effect of this indisposition, in this State, at this time, is, that any person may control the issues of human life and death as a doctor,—or as a pharmacist may buy, recommend, and sell the most deadly medicines without adequate knowledge of them, and without control.

In deference to this policy of the Legislature of this State, whether the policy be wise or not, this Society earnestly recommends that the educational policy long established in the common school system of the State be extended to pharmacy by offering to students of that art a more extended means of acquiring competency. The plan would be to supply liberal adequate means for acquiring education in pharmacy, with due notice that after a reasonable time penal law would establish a standard of qualification, and enforce a reasonable responsibility for careless and ignorant acts.

There is one chartered College of Pharmacy in this

State, which has struggled along for many years through poverty and adversity, almost unsupported by either law or popular favor, whose object has always been to do that for which legislation is now popularly demanded. Properly enlarged and supported this institution might be sufficient for the present wants of the State, at least so far as to try the value, in practical operation, of the educational plan long since endorsed by the Legislature in the charter of the College.

This New York College of Pharmacy is now, or will be, petitioners to the Legislature during its present session for pecuniary aid to enable it to extend and better carry out its educational purposes.

Therefore, be it resolved, That this Society deprecates any action on the part of the Legislature whereby any new offices or inspectorships may be created, at least until other more reasonable means be tried—first, because examinations and inspections can neither educate persons nor otherwise secure competency; and second, because experience has shown in other States and countries that such plans are very partial in their effects—very apt to degenerate into abuses—and that their ultimate expense to communities is greatly out of proportion to the good obtained in the result.

Resolved, That the Medical Society of the State of New York heartily endorses the objects of the New York College of Pharmacy as set forth in the accompanying petition of its Board of Trustees, and desires that the petition may be granted.

Resolved, That a copy of this preamble and resolutions, authenticated by the signatures of the President and Secretary of the Society, be transmitted to the Senate and Assembly through the presiding officers of these bodies.

New York, January, 1871.

We, the undersigned, trustees and members of the College of Pharmacy of the City of New York, do hereby most respectfully petition the Honorable the Legislature of the State of New York for aid to enable the trustees of said college to extend its labors in advancing Pharmaceutical Science. We most respectfully submit herewith a few points to the kind consideration of your honorable body.

The College of Pharmacy of the City of New York was incorporated April 25, 1831, for the purpose of cultivating, improving, and making known a knowledge of pharmacy, its collateral branches of science, and the best modes of preparing medicines and their compounds, and of giving instruction in the same by public lectures. Since the commencement of its labors the college has granted about 150 diplomas, and has furnished about 200 lectures each season. There are only six Colleges of Pharmacy in the United States, this college being the only one in the State of New York; and young men desirous of obtaining its diploma, on applying to a committee of the college, expressly appointed for that purpose, are aided in obtaining positions in first-class pharmaceutical establishments, so that even persons from the remotest part of the State may reap its benefits.

The annual income of this college, from all sources, depends almost entirely on voluntary contributions by the pharmaceutical fraternity, and has so far only been sufficient to supply defective apparatus, to pay the lecturers, and to make fragmentary additions to its collections, without enabling it to increase the latter to such an extent as the recent rapid strides in science demand.

At present it is imperatively necessary to increase the number of, and to more adequately compensate the lecturers (who are the only persons receiving salary from the College), to procure collections of standard botanical, mineralogical, and chemical specimens, to obtain a large lecture-room with a chemical and pharmaceutical laboratory, and to make numerous additions to the library—for the procurement of all of which the funds of the College are totally insufficient.

In view of these wants, and since it is all-important that persons devoting themselves to pharmacy should have the proper scientific education, in order to be qualified for their responsible position, and to enable the College to combat ignorance and incompetency, which endanger the health and often the lives of the people, your petitioners most respectfully ask the Hon. the Legislature of the State of New York for aid, in the sum of $10,000, to assist in carrying out the above mentioned designs of the College. Such a public acknowledgment will most certainly be in many ways a benefit not only to the city of New York, but to the State at large.

Confidently relying on the justice of our humble request, and on the wisdom of your honorable body, your petitioners will ever pray.

After a brief discussion the mover withdrew the preamble and resolutions, because of insufficient time to consider so important a subject.

THE NIAGARA COUNTY SOCIETY.

The Committee on Ethics to whom the Niagara County difficulty was referred, reported in favor of the minority forming a new Society.

COSTS IN MALPRACTICE.

Dr. E. Eliot offered the following:—

Whereas, The bill before the Legislature to secure physicians in the payment of costs and damages in suits for malpractice, by compelling the plaintiff to give satisfactory bonds before the commencement of any suit, is one of the highest interest to every physician; Therefore

Resolved, That this Society respectfully requests the Honorable Legislature to pass the same.

Adopted.

After the usual vote of thanks to the President and Secretary, the Society adjourned until the first Tuesday in February, 1872.

Progress of Medical Science.

Pepsin and its Medicinal Preparations.—Dr. Fred. Hoffmann, of New York, relates, in a recent publication in the Proceedings of the American Pharmaceutical Association, a series of comparative examinations of the French as well as of the American commercial dry pepsins, by which he has satisfied himself of the well-founded disfavor into which this remedial agent has fallen with the practitioner. The author refers to similar results recently published by Dr. Hager, of Berlin (*Pharmac. Central Halle*, 1870), wherein Dr. Hager states that this remedy had been in discredit with him for years, but that his attention had been drawn to pepsin anew by the remarkable efficacy of Schering's recently introduced "Essence of Pepsin," prepared from dried ostrich's stomachs, at the advice of Dr. Oscar Liebreich. Dr. Hager examined, and gives in his paper the formulas of, the French liquid pepsin preparations. He found none of them equal in efficacy to Schering's preparation, which dissolves, at the temperature of the human body, one-tenth of its weight of humid blood-fibrin within one hour.

Dr. Hoffmann concludes his paper, "According to long experience and to the numerous and recent statements of eminent practitioners and observers, there remains no doubt that pepsin, when properly obtained and prepared, is of great therapeutical value in cases where the secretion of the gastric juice is either de-

ficient in quantity or defective in quality, and that the discredit attributed to it is due to the inferior quality of the pepsin-preparation, and to the defective mode of obtaining and preparing the same. It ought to be the aim, and lies in the self-interest of the pharmaceutist, henceforth to remedy the unreliability of this important preparation, and so furnish the practitioner and the patient with a pepsin in the most judicious form of preparation.

"In order to secure this desideratum I think it necessary to discard all amylaceous and similar so-called dry pepsin. Being a remedial agent of no chemical stability, and perhaps in a state of continuous self-decomposition when in contact with organic substances and with the atmosphere, our dry amylaceous pepsins are subjected to constant and incidental degradation. Sooner or later they will lose all medicinal power, and become totally inert. I believe that the best mode of obtaining and preserving the pepsic principle of the gastric juice of the stomach is its incorporation into inactive liquid menstrua without any chemical treatment, as is the case in Boudault's process, and in that of the French code. The simplest possible menstruum, perhaps, may be a mixture of glycerin and water, with or without an addition of some per:entage of alcohol flavored with any artificial wine or fruit essence. The quantity of alcohol, however, ought not to exceed ten per cent., since a greater admixture probably neutralizes the therapeutic action of pepsin.

"The best mode of obtaining the gastric juice from the cleansed, fresh stomachs of the calf, pig, sheep, or of the turkey, is to squeeze them repeatedly between wooden rollers. After all the juice has been squeezed and collected with silver spoons, the membranes are each time, before again passing through the rollers, brushed with a mixture of equal parts of water and glycerin. By this operation, the membranes are thoroughly exhausted. According to our present experience, it may be best to add to the obtained juice a mixture consisting of twenty-five weight parts of glycerin, two parts of hydrochloric acid, eight parts of alcohol, and sixty-five parts of water, deprived of atmospheric admixture by previous boiling. But in order to make the preparation more agreeable to the taste I use instead of the water good Rhine wine, which by its simplicity and greater reliability as to its genuineness is greatly preferable to our commercial Madeira, sherry, and port wines. The mixture is then left in a very cool place (in summer in the ice-box), to deposit, in bottles entirely filled and well corked. When clear it is decanted, the rest filtered, and is then kept in a cool place in small bottles completely filled and tightly closed. The addition of hydrochloric acid may not be necessary, but it seems to be subservient to the clarification of the mixture.

"As to the strength of this pepsin wine, there is no standard established yet. I prepare it of the strength, suggested by Dr. Hager, to dissolve twelve and a half parts of its own weight of humid blood-fibrin."

THE CONSTRICTING SILVER LIGATURE IN ANEURISM.—Dr. Benjamin Howard, of New York (*Trans. Am. Med. Association*), in his Prize Essay on the "Treatment of Aneurism," advocates the *constricting silver ligature*, and offers the subjoined practical suggestions concerning the steps of the operation:—Every precaution should be taken to avoid anything which might interfere with the healing of any part of the wound by first intention. For the arrest of hemorrhage in the wound, cold affusion, ice, pressure, or torsion should be substituted for ligature. The medium size of the silver ligature is preferred; not so small as to have too much tendency to cut, nor so large as to make a clumsy knot. The disturbance of the artery in its bed should be as little as is consistent with the safety of the accompanying vessels. In his later experiments, the ligature was applied outside the sheath of the vessel, and this he would recommend, because the nourishment of the arterial coats is less endangered, absorption of the external coat from pressure of the ligature is postponed or avoided, and the advantages of ordinary indirect compression are more nearly obtained, without risk of pain or sloughing, while the diminution of the arterial current can be regulated with greater accuracy. Before using the wire, it is better to test its strength, and to draw it repeatedly through woollen cloth, so as to remove any irregularity, and to give it a good polish. The wire should not be less than 15 or 18 inches in length, as this contributes much to steadiness in the tying of it. Dr. H. would give the constricting silver ligature preference to any other treatment for closure of the carotid or subclavian, not because it is more likely to succeed there than elsewhere, but because there are other means more apt to fail. The constricting silver ligature is, he believes, essentially adapted to the cure of aneurism equally in the other arteries, while it promises success where no other treatment would be readily practicable.

TOPICAL MEDICATION IN THE TREATMENT OF ENDO-METRITIS.—J. Byrne, M.D., Surgeon to St. Mary's Hospital, Brooklyn, N. Y. (*Trans. Am. Med. Association*), gives the following opinions touching the safety and value of topical medication in the treatment of endo-metritis:—By means of a proper reflux catheter—such as described in his paper—in the hands of experienced and cautious practitioners, tepid water, antiseptic, mildly astringent, stimulating, or alterative solutions may be thrown into the uterine cavity with perfect safety, and, provided the same be judiciously selected and modified to suit the prominent indications of each particular case, a degree of success, so far as topical measures can influence, is in no other manner attainable. On the other hand, powerfully astringent liquids and caustic substances destructive to tissues with which they may be brought in contact, or tending in any great degree to coagulate morbid secretions, are not safe as a rule, seldom if ever necessary, and often dangerous, however carefully or sparingly employed. The strictest regard must in all cases be had to dietetic and hygienic measures, with such other constitutional treatment as may seem demanded.

LIQUID FOR THE PRESERVATION OF WET ANATOMICAL PREPARATIONS.—Dr. B. Titcomb, of Maryland (*Trans. Am. Med. Association*), advocates the subjoined method for keeping objects of pathological anatomy and for the purposes of dissection:—First place the object in a vessel containing pure water; let it remain a few hours, or over night, then transfer it to another containing a solution of creasote, ʒ ij. to f ʒ xij. of water; let it remain over night, then place it in a jar or vessel containing the liquid of the following proportions: ℞. Chloride of sodium, ʒ iss.; sulphate of alumina, ʒ iss.; nitrate of potassa, ʒ vj.; aqua, f ʒ xij.

MALIGNANT TUMORS.—According to Virchow (*N. Y. Med. Journal*), the mortality-lists in the department of the Seine for the years 1830–40 indicated 9,118 deaths from malignant tumors. In 2,996 cases, or 32.8 per cent., the uterus was the organ affected. The proportion for the other organs was as follows:—

Stomach	2,303 or 25.2	per cent.
Mammary Gland	12.6	" "
Liver	6.9	" "
Intestines	4.0	" "

THE SEAT OF TUMORS.—Virchow (*N. Y. Med. Journal*) states that those organs which possess a soft surface, and are often brought in contact with foreign bodies, are oftener the seat of tumors than those which are shut up in cavities, and are rarely brought in contact with outside influences.

TREATMENT OF HEMORRHOIDS.—Dr. John H. Packard, Surgeon to the Episcopal Hospital, Philadelphia (*N. Y. Med. Journal*), says, that one principle should govern us in all the palliative measures adopted in any case of piles: namely, to prevent straining. And this may be carried out in various ways. Besides the adoption of a proper diet-table, embracing simple but nutritious food, well cooked, and not highly seasoned, there are four points to be attended to. By means of medicine we keep the bowels easily moved; ʒ ss. or so of sulphur, mixed with cream or molasses, every morning before breakfast, will do this. Or, by very small doses of Epsom-salts, by Vichy, Congress or Bedford water, we may accomplish the same end. The second measure is mechanical: the patient is instructed to have made a board, with an opening about five inches wide by fourteen long, to place over the ordinary privy-seat, which allows the nates to bulge down too much; this will in a great degree prevent the protrusion of the relaxed rectum. The third is the use of astringent suppositories, to be used after each stool. He has found the perchloride of iron, grs. j, ij, or iij, made up with cacao-butter, to answer best, unless the piles are inflamed, when the acetate of lead is more soothing. The fourth element of the treatment is the employment of a hemispherical block of ivory or vulcanized rubber, about as large as half a billiard-ball, attached to a spring of properly adjusted strength, and this again fastened to a belt. When in place, this supports the parts, and in cases of great relaxation prevents their descent in walking; the comfort thus afforded is very great.

CARBOLIC ACID IN CARBUNCLE.—Dr. J. C. Nott, of New York (*N. Y. Med. Journal*), advocates the local use of carbolic acid in carbuncle, and publishes an obstinate case which was promptly cured after seven applications. He believes this acid to be more penetrating in its action, more efficient as an antiseptic, than subsulphate of iron.

THE ADMINISTRATION OF CHLORAL.—E. Lambert, late House Surgeon of the Maternity Hospital, Edinburgh (*Edinburgh Med. Journal*), affirms that the proper mode of exhibiting chloral is in fractional doses of 15 grs. every quarter of an hour until some effect is produced. Some patients will require doses of ʒ j.; and it is better to produce an anæsthetic effect by ʒ iij. given in the space of two hours than by ʒ j. given singly.

A CASE OF FOREIGN BODY IN THE TRACHEA.—Dr. O. W. Doe, Boston, Mass. (*Boston Med. and Sur. Journal*), publishes an interesting case, where a shawl-pin was swallowed by a child 28 months old, remaining in the trachea thirty-three days after the accident, and finally removed by tracheotomy. The incision, extending from immediately below the cricoid cartilage to the upper border of the sternum, was made through the skin and superficial fascia, and the sterno-hyoid and sterno-thyroid muscles separated, avoiding the thyroid plexus of veins. About ten minutes after the trachea was opened, the patient gave a forcible cough, and the point of a pin was seen to strike the internal wall of the trachea at the edge of the incision, and was immediately seized by the forceps and extracted. The pin was a medium-size shawl-pin, one and a half inches in length, with a glass head. Four days after the operation, the trachea had closed over. The patient made a speedy and perfect recovery, with no untoward symptom, except a slight attack of catarrhal croup on the sixth night. He remarks in closing, that he has only been able to find four cases where tracheotomy has been performed for the removal of either a pin or needle, but a large number for the removal of other foreign bodies of a diversified character.

SULPHO-CARBOLATE OF ZINC.—This salt crystallizes in large, colorless crystals, having the peculiar astringent metallic taste of the zinc salts generally. Dr. Lyons, of Detroit, Mich. (*Detroit Review of Medicine and Surgery*), confirms the views of others in the successful treatment of gonorrhœa by a solution of sulpho-carbolate of zinc. It is highly recommended as a dressing for burns. The solution for the former purpose may be made as strong as eight or ten grs. to the ounce, if the crystals are used. For the latter use a much stronger solution may be employed. The advantages claimed for the sulpho-carbolates are, that while they possess decided antiseptic properties, they have no disagreeable odor, and their action is more gradual and permanent, although necessarily slower than that of the volatile carbolic acid.

STRANGULATED HERNIA.—Dr. S. D. Gross, in a recent clinical lecture at the Jefferson Medical College, on strangulated hernia, mentions the fact that tobacco enemas are no longer employed. Leeches and venesection are made use of less at the present day than they should be. With great local tenderness and a plethoric patient, they diminish the dangers of gangrene in the protruded structures, and the occurrence of general peritonitis. Chloroform has advantageously superseded the use of the warm bath. This anæsthetic has a decided preference over all others; with proper care in its administration it is equally safe; it possesses the advantages of greater promptness of action, and much less liability of unpleasant and protracted secondary effects, as nausea, vomiting, etc. Vomiting should be sedulously guarded against in the treatment of strangulated hernia, on account of its injurious effects upon the constricted bowel, and the danger of a recurrence of the protrusion. Chloral, in thirty gr. doses, promises to be a valuable remedy in the treatment of strangulated hernia, rapidly inducing sleep, and relaxing the system.

SPEEDY AND SPONTANEOUS RECOVERY FROM RUPTURE OF RECTUM AND BLADDER.—Dr. O. C. Gibbs, Frewsburg, N. Y. (*Buffalo Med. and Surg. Journal*), relates the case of a man, aged 55, who, while pitching hay off a wagon, fell backwards on to a sharpened stake of the rack. The stake entered the anus so centrally as to show very little signs of injury, but passing up severely lacerated the rectum and bladder. Falling still farther, the stake was broken off and withdrawn by his co-workman. The ash stake was 1¼ inches in diameter, and full a foot in length. For four days after the accident the urine was passed per rectum. From that time he began to pass urine slightly by the urethra, and after a few more days he had full control of the urine and passed it by the urethra. After about two weeks from the date of the injury he was out doing light work, and, after a few weeks more, went to work on a railroad with shovel and barrow.

This is one of those cases manifesting strong natural recuperative powers—as he absolutely refused treatment. A strong desire and determination to live for his family, residing in Sweden, had probably some influence over the result.

VARICOSE VEINS.—C. C. F. Gray, M.D., Buffalo, N. Y. (*Buffalo Med. and Surg. Journal*), during his pres-

ent term of service in the Buffalo General Hospital, has radically cured two cases of varicose veins by the use of potassa cum calce. He prefers this method to any other, being safe, almost painless, and successful.

The first patient treated, aged 26 years, had enlarged veins, the result of general debility. Five eschars were produced upon the left leg, and three upon the right. In four weeks he was discharged cured.

The second patient, aged 61, had a varicose ulcer, and varicose veins, upon his left leg. Potassa cum calce, made into a paste by alcohol, was applied directly over the enlarged veins at five points. In twenty minutes the paste was washed off with vinegar. The eschars thus made were of the size of a pea. At the expiration of six weeks the eschars had not only healed, but also the varicose ulcer. The cure seems to be radical. When the patient is standing up the leg looks smooth, and there exists no longer any appearance of enlarged veins.

Stricture of the Urethra.—Preceding the operation on a stricture, Dr. Alexander W. Stein, New York (Retention of Urine depending upon Stricture), is in the habit of administering quinine, in five-grain doses, three or four times daily for a few days. It will often diminish, if not prevent, the occurrence of rigors, a symptom so exhausting to the patient. Opium is a desirable adjuvant, and may be combined with the quinine. Occasionally, however, this drug is inadmissible, especially during the existence of renal disease. He has recently employed chloral hydrate with satisfaction, in allaying the irritation consequent upon operations about the urethra.

Instruments should not be introduced too soon after the operation; pain and considerable irritation are produced without a corresponding amount of benefit being derived. In three of his recent operations for internal urethrotomy, no instruments were passed until three weeks after the operation.

Hydrate of Chloral in the Treatment of Congestion of the Retina.—Dr. Russell Murdock, member of the Baltimore Pathological Society, in a discussion on the impairment of sight by hydrate of chloral, replied that it is stated in the ophthalmological journals to cause anæmia of the retina, and suggested that it might prove useful in treating congestion of its vessels, for which artificial leeching is now the remedy.

Radical Cure of Artificial Anus.—F. W. Draper, M.D., Boston, Mass. (*Boston Med. and Surg. Journal*), thus describes M. Goyard's new method of operation for the radical cure of artificial anus: The real indication to be fulfilled is to prevent the escape of the intestinal contents between the lips of the opening. For this purpose a suture is passed near the margin of the orifice, so that it is placed deeply, and draws together tightly the hardened and callous cellular tissue which forms the wall of the canal. The suture, which should be strong and smooth, is passed deeply from side to side, just below the lower extremity of the orifice; then subcutaneously a little distance, then back again to the other side, and so on until the opening of the anus is all involved in this series of transverse stitches; a second suture passed in the opposite direction, the same points of entrance and exit in the skin being observed, completes the circuit and enables the operator to readily oppose and retain the walls of the fistula. The needle used is one of moderate curve, with the eye near the point. After the sutures are passed, the surface of the fistulous tract is thoroughly refreshed, and its external edge is drawn together by an ordinary interrupted suture. The lesion is reduced to a simple wound, and union by first intention may be expected if the general condition of the patient is good. One argument in its favor is, that the patient is not obliged to undergo an operation, properly so called, and does not suffer any loss of tissue.

Case of Extra-Uterine Pregnancy.—A case of this rare kind of pregnancy, occurring in a colored woman aged 35, who had been pregnant between four and five months, is reported by Dr. Talbot Owen, Louisville, Ky. (*Richmond and Louisville Med. Journal*). The tumor, situated in the left inguinal region, was diagnosed as ovaritis, with circumscribed peritonitis. About six weeks from his first visit she died. Five days before her death the pulse rose to 165. On post-mortem examination the placental membranes were found adherent to the broad ligament of the left side of the uterus. The date of rupture of membranes and hemorrhage is located on the day when the pulse ran up to 165 beats per minute, by which hemorrhage the mode of death was from syncope, he thinks, and embraced both of its divisions, asthenia and anæmia.

Chloroform in the Treatment of Biliary Calculi.—John Barclay, M.D., Physician to Leicester Infirmary (*British Med. Journal*), recently gave to a clergyman, aged 58, in his third attack from gall-stones, chloroform in two- or three-drop doses, three or four times a day, and to his surprise pain, tenderness, distension, and jaundice disappeared together.

Treatment of Irritable Heart.—Dr. J. M. DaCosta, Philadelphia (*Am. Journ. Med. Sciences*), in his treatment of irritable heart occurring in soldiers, with hypertrophy, states that no medicine can be compared to aconite. In moderate doses, used for months, a decrease of the enlarged organ happened. In pure irritable heart he recommends digitalis, digitaline, and veratrum viride—the latter stands between aconite and digitalis. Ten drops of the tincture of digitalis were given three times daily, and from $\frac{1}{60}$th to $\frac{1}{30}$th of a grain of digitaline, to some of his soldier-patients. He is disappointed in gelseminum as a cardiac sedative. In instances of irregular action, belladonna and atropia proved very efficient agents.

Acute Atrophy of the Liver.—A case of this rare disease, occurring in a merchant, aged twenty-three years, is reported by Isaac G. Porter, M.D., of New London, Conn. (*Am. Journ. Med. Sciences*). The liver was examined microscopically, and showed entire absence of the cell-element. He regrets to say that it was not weighed. It was so small, however, that on opening the cavity of the abdomen, the universal inquiry among bystanders was, "Where is the liver?" since it had shrunk so much as to have nearly vacated its normal position. The influence of miasmata, while spending a month of April in Savannah, Georgia, was supposed to have been the cause. He was a man of excellent habits, and living under happy mental and hygienic influences.

Fibrous Tumors on the Lobes of the Ears.—Dr. C. H. Burnett, of Philadelphia (*Am. Journ. Med. Sciences*), refers to six cases of recurrent tumors, occurring in negresses, which confirm the statement made by Tröltsch, that these tumors are due to the improper treatment of the pierced lobes, and are usually found in negresses.

The Value of Emetics.—Dr. J. G. Stokes, Grayville, Ill. (*Chicago Med. Examiner*), presents the claims of emetics, given during pregnancy, to the favorable consideration of physicians. He finds that in cases of threatened abortion, miscarriage, and premature labor

they have, in his practice, acted with more promptness, and with more permanent good results, than every other known remedy combined. In attempting to discover the *modus operandi* of an emetic in cases of abortion, miscarriage, and premature labor, its powerful revulsive effects should not be overlooked. It unlocks and restores the secretions, and has a happy effect in righting up the digestive apparatus, and relieves the distress during pregnancy, of sour stomach, heartburn, etc., and tends to regulate the bowels by restoring the secretions. It also has a very decided effect upon the nervous system.

Treatment of Chronic Hydrocephalus.—Dr. N. S. Davis, Chicago, Ill. (*Chicago Med. Examiner*), advocates the subjoined prescription in the treatment of chronic hydrocephalus:—℞. Fl. ex. scutellaria, ℥ ij.; tinct. digitalis, ℥ ss.; iod. potass., ʒ ij.; fl. ex. hyoscyamus, ℥ ss. M. Dose, twenty drops, four times a day, in sweetened water. If the digitalis is found to be exerting too much influence, the dose must be diminished.

Median Lithotomy.—Dr. James L. Little, surgeon to St. Luke's Hospital, N. Y. (*Transactions American Medical Association*), reports twelve cases in which this operation was performed, and only two deaths occurred. He also adds ninety-six American cases, with three deaths. Thirty-nine were under ten years of age, twenty from ten to twenty years, and thirty-six from twenty to sixty-nine years. This gives an average mortality of one in forty-seven and a half as opposed to one in eight, the average in lateral lithotomy. Excluding the fifty-nine cases under twenty years of age, the mortality is one in eighteen in cases ranging from twenty to sixty-nine years; a result far exceeding that of any other form of operation.

Modern Surgery.—An illustration of the advance in surgery made in the present century may be found in the fact that the operator who first successfully tied the internal iliac artery for aneurism, Dr. Stevens, died only two years ago. Dr. S., who then lived in the West Indies, was only twenty-six years of age, in 1812, when he achieved this feat. Nine other operations of the kind, performed since, are upon record, with four successes, so that the proportion of deaths is only 50 per cent.—*Richmond and Louisville Medical Journal.*

The Use of Unctuous Substances in the Lying-in Chamber.—Dr. Wm. Goodell, of Univ. of Penn. (*Am. Journ. Med. Sciences*), wishes to add his protests to those of Mauriceau, La Bas, Denman, Roederer, Gardien and Gehler, against the indiscriminate use of lard and of other unctuous substances, so universally found in the lying-in chamber. For this error the profession is indebted to the ancients, who borrowed the idea from the trainers of their athletes.

His own practice is to discard the use of lard, to let the vagina alone, and to content himself with keeping the cutaneous surface of the perineum well smeared with the surplus mucus which escapes from the vulva.

Abscess within the Cranium.—Professor Nathan R. Smith, of Baltimore, M.D. (*Baltimore Medical Journal*), in 1869, trephined an Episcopalian clergyman, of Virginia, and removed a button of bone about seven-eighths of an inch in diameter. There immediately issued three ounces of fetid pus. The patient was injured twenty years before, by an accidental blow from a sharp stone, on the left parietal bone. It was followed by inflammation of the pericranium, necrosis, and a final separation and discharge of a small sequestrum, involving both tables of the bone. There remained a fistulous opening, which never closed during the twenty years. It so little interfered with his general health that he continued, during that time, to discharge the duties of his calling, though occasionally suffering pain in the head and vertigo, especially when the discharge was in any way impeded. No morbid phenomena followed the operation. By inspection, and by the probe, it was ascertained that the dura-mater was slowly rising, and the cavity being obliterated. Dr. Smith saw his patient last summer on his way to the Episcopal Convention. He had entirely recovered.

Asthma.—In an interesting discussion on the management of asthma, by the members of the *Baltimore Pathological Society*, Dr. Garretson (*Baltimore Medical Journal*) alluded to the case of Colonel Washington, subject to attacks of this affection lasting four or five days, who was relieved in two days by bromide of potassium and belladonna.

Fracture of Neck of Femur, with Inverted Foot.—Dr. A. S. Hudson, Stockton, Cal. (*Pacific Medical and Surgical Journal*), reports a case of this character, occurring in a male adult, who, in a state of intoxication, had fallen down a flight of stairs. It was plainly a case of fracture of the neck of the femur, with impacted fragments. His chief object in communicating this case, is to contribute to the surgical history of this fracture. Hamilton says:—"In sixty cases of fracture of the neck, seen by Cloquet, the foot was never turned in; and Boyer never met with an example in all of his immense experience; but Langstaff, Guthrie, Stanley, and Cruveilhier have each seen one example." Hamilton has seen one.

Skin-Grafting Superseded.—Recent statements on the interesting subject of skin-grafting seem to show that they were mistaken who at first thought it necessary to transplant pieces of skin of any depth. All observers now agree that the first phenomenon is the disappearance of the characters of true skin in the piece transplanted, which becomes a mere pellicle. Further, there should be no trace of areolar or adipose tissue left, and Dr. Fiddes says that there is no necessity to take any skin, but merely a few epidermic scales.—*Med. Press and Circular.*

Aloin.—T. and H. Smith, chemists, of Edinburgh (*Pharmaceutical Jour. and Trans.*), assert that if it be admitted that aloin is the active purgative principle of aloes, one manifest advantage from using it would be that we have therein a medicine of unvarying strength; and we possess what we judge to be conclusive evidence that there is no other substance of value in aloes, and that in all cases where aloes of best quality will produce purgation, a proportionate dose of aloin will be of equal and more certain effect. This preparation is now extensively used in England and Scotland; and since its first discovery the manufacture, by these chemists, has increased from a few pounds to many thousand ounces yearly. They find the dose requisite to be aloin to aloes, as one is to five.

The Removal of External Hemorrhoids.—Dr. John H. Packard, Surgeon to the Episcopal Hospital, Philadelphia, is satisfied that the écraseur affords the easiest and best means of dealing with external hemorrhoids. He passes two needles (the curved are the most convenient), at right angles to one another, through the base of the hemorrhoidal mass, and separates it once. By keeping the bowels confined with opium until the healing is accomplished, the patient suffers no pain, and above all is relieved by one single procedure; there is nothing left to come away.

THE MEDICAL RECORD.

A Semi-Monthly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

THE PROCEEDINGS OF THE STATE MEDICAL SOCIETY.

THE variety and importance of the subjects brought up for the consideration of the State Society gave much interest to its recent meeting. Though not as largely attended as on previous years, those who took part in the proceedings were actuated to a man with the proper motives of mutual benefit and profit. The papers were all good and practical, and the extreme length of some was counterbalanced by the practical good which they accomplished. The most notable of these we shall present at some future time in full to our readers.

We were sorry to have the proper harmony of the meeting disturbed at one time, by the outcroppings of a bitterness of feeling between the hostile parties at Albany. We confess ourselves unacquainted with all the details of the ill-feeling between the friends of the College, on the one hand, and the other members of the profession on the other, nor should it concern us in our journalistic capacity, but we do not desire to be enlightened in any society meeting. We emphatically protest against the ventilation of local matters before an audience of outsiders. There is too much temptation in the excitement of the moment to be unfair, unjust, and to yield to personalities. This was apparent, we are pained to say, on the occasion referred to, and resulted in prejudicing the interests of both sides. No society as such can take an interest in private differences, and it is not only wrong but presumptuous for the parties involved to expect it. We are pleased to note that the affair was promptly checked by the President.

A novel feature in the meeting was a charge of plagiarism against the author of a paper in the Transactions for the year 1868. This charge was made by a member who has always had the confidence and esteem of the members, and in that respect was the more grave and significant. The facts are curious enough, to say the least, and we are sorry that they are not better or more satisfactorily explained. It seems that the article in question is made up mostly of a literal copy of a work on Hygiene by Dr. Parkes, of London, without any credit given therefor. In explanation the appropriator of the labors of Dr. Parkes says that a preface was written in which full credit was given, but that this preface was by some oversight not published with the paper. It further appears that this oversight was due to the writer of said paper, as the preface was not handed along with the paper to the Committee on Publication, and that it was not supplied after the proof of the article was sent him, neither were any quotation marks used. Another curious circumstance is the fact that the volume in which the article appeared had been in Dr. Thoms's hands a full year without any expressed regret that Dr. Parkes did not receive the credit which was his due. If the statement of the compiler is true, that the preface was actually written, and we have no right to say that it is not, it is an instance of culpable negligence unbecoming a conscientious man who is willing to stand strictly on his own merits. The Society did well in passing the resolution of Dr. Squibb; and it is to be hoped that the outraged author may be satisfied that its mebers do not wish to hold themselves responsible for the negligence, to say the least, of one of their number. The Society also passed a vote accepting the excuse of Dr. Thoms, as to intention of wrong, more for the sake of charity to him than of justice to the spirit of the resolution.

The question of the Niagara County Society was a very knotty one to deal with, and we do not see how the adoption of the recommendation of the Committee on Ethics, that the minority form a new society enjoying the right of representation to the exclusion of the others, can remedy the difficulty. Here is a case in which a society is not willing to discipline its members in accordance with the code of Ethics. The right-minded members are so much in the minority that they have no resource but to secede. On the face of it this is right; but how the present statute can be construed to permit it is a matter which we cannot comprehend. But we shall probably have more to say on this general topic in future.

The protests from several county societies regarding the election of permanent members from districts to which they do not belong show a strong opposition to a prevalent practice. The ground taken by these counties is perfectly right; each county society has the right to have its own members who are eligible made permanent members, to the exclusion of outsiders, and they should demand it. The rule should only be departed from when there are no candidates from the counties for the election, and then and then only should substitutes be named.

The addresses of the President were deservedly well received. The suggestions in his inaugural were wise and just what were needed, as evinced by the hearty endorsement of his views by the several committees to whom the respective topics were referred. The annual address was a model of its sort, evincing great research

and practical application. We sincerely trust that it may have its effect in stimulating the proper study of pathological anatomy, not only among its members, but throughout the profession of the country.

The lecture of Dr. H. D. Noyes was also a feature of the meeting, and was a complete success. The admirable manner in which he presented the points of so abstruse a subject as astigmatism, and his beautiful and striking illustrations with the magic lantern, were deservedly appreciated by the audience.

The choice of President belonged to the city, but there was so much disagreement in the nominating Committee as to whom the nominee should be, that it was deemed best to select a gentleman from another part of the State. They could not have done better than confer such honor upon Dr. W. C. Wey, of Elmira. When his name was announced by the Committee the Society showed itself more than pleased with the choice. For many years he has been a faithful attendant upon the meetings; and, aside from contributing his share to the Transactions, has by much hard committee-work proved that he has always had the true interests of the Society at heart.

It was according to rule that Dr. W. H. Bailey, of Albany, was re-elected Secretary. The Society has seemed to be right thus far in assuming that no other gentleman can be found who can perform the duties of this onerous office to more satisfaction.

The prompt and unanimous passage of the resolutions endorsing the course of Dr. Sayre in the malpractice suit was a very flattering compliment to that gentleman, and may be considered as of special interest to the profession at large. The State Society of Pennsylvania must not forget a like expression of their opinion in regard to a similar suit against Prof. Reese, of Philadelphia. But we have already given our views in regard to the course of these gentlemen, and they need not here be reiterated.

Dr. Squibb, of Brooklyn, presented some very important resolutions concerning the sale of poisons, etc., but the discussion of this, as well as other matters of interest, must be deferred.

For many years past it has been the aim of the medical men of this city, particularly those connected with the Coroner's office, to procure the conviction of abortionists. During that time several cases have come to the notice of these gentlemen, in which the medical proof as to the act of crime was overwhelming; and to those uninitiated in the quibbles of the law, and the influence of large counsel fees, it seemed impossible for the criminals to escape. But sometimes law is one thing and simple justice another, and so it has heretofore proved to be as a rule. This being the conclusion to which medical men had come, it must strike not a few with surprise to learn that an acknowledged and bonâ fide abortionist of this city has not only been caught, has had his guilt established, but has been sent to State Prison for the full time allowed by law. Judge Bedford, the son of the well-known and recently-deceased Professor of Obstetrics, was the means to such a desirable end, and the profession and community at large cannot be too grateful to him for the noble stand he has taken.

It seems that, last June, Michael A. A. Wolff called upon a female six months advanced in pregnancy, and by the introduction of an instrument ruptured the membranes, and produced miscarriage, which was shortly after followed by metritis and death. Drs. C. C. Terry and Beach made the autopsy, and succeeded in establishing, in a straightforward manner, the cause of death. The District Attorney took up the prosecution with a will, and succeeded, in spite of every effort to the contrary on the part of the counsel for the prisoner, in making out a clear case.

The charge to the jury showed the judge to be fully alive to the importance of the case; and while desiring to give the prisoner every benefit of doubt to which he might be entitled, there was a determination on the other hand to inflict upon him the most severe punishment. In proof of this we cannot do better than present to our readers the concluding clause of said charge:—

"In conclusion, gentlemen, permit me to say a sacred responsibility now devolves upon you. You are twelve men, selected by the people, on the one hand, and the prisoner on the other, to determine under the solemnity of your oaths a question, not only vital to the prisoner, for his future liberty depends upon it, but momentous to each and every citizen of the Commonwealth. The eyes of the community are upon you. The hopes of the unhappy prisoner hang, as it were, upon your very lips. Let no false sensibility influence your judgments. Your duty is to be just. Look to the evidence in this case; analyze it with a scrutiny worthy of your position as jurors, sworn without prejudice or bias to sustain at all hazards the truth, and in thus sustaining the truth to vindicate the majesty of the law. You are to look neither to the right nor to the left in arriving at your verdict. The great and only lever of thought and action is the testimony as it has been presented to you. Let your verdict be rendered in accordance with that testimony, so help you God. And should you be convinced of the prisoner's guilt beyond that reasonable doubt which the law declares to be the property of the accused, then I ask you, for the protection of unborn millions, be prompt in the rendition of your verdict, thereby declaring in unmistakable language that such a burning shame and so gross a violation of the laws of both God and man shall not be permitted to escape the punishment due so monstrous a crime, perpetrated in the very heart of a community professing to be Christian, and to be governed by law and good order."

The verdict of the jury was "guilty of manslaughter in the second degree, with a recommendation to mercy." The unwillingness of Judge Bedford to entertain the latter clause of the verdict is to be seen in the request made of one of the District Attorneys to state the antecedents of the prisoner, which proved him to be a deep-dyed criminal, and one who had been prac-

tising child-murder for years. The jury on hearing this, to their credit be it said, to a man withdrew the recommendation; and the Judge, in passing sentence, made use of the following language, which, coming as it does from one who not only means what he says but has the power, the determination, and the courage to enforce such promises, is encouraging to every right-minded citizen:—

"The people may rest assured that the District Attorney, Recorder, and myself will give, on all proper occasions, every assistance to crush out this monstrous crime and to banish from our midst these traffickers in human life. In one word, the authorities have declared war to the bitter end against the fraternity which you to-day so guiltily represent. Let every professional abortionist, male and female, rich or poor, in this city take warning, for, on conviction, their fate shall be the same as yours—namely, confinement in the State Prison for the period of seven years, the longest term allowed under the statute."

Thus endeth the first case of conviction for many a long year; and may we not hope, in the interests of future generations of innocents, that it may be the commencement of a rule of terror with the numberless abortionists who have heretofore carried on their trade with a boldness that has only been equalled by its wickedness.

The only pity, is that the law is not stringent enough to give the full measure of punishment to these malefactors. Let this circumstance be taken into account in the framing of the new law for the punishment of the crime now before the legislature. State Senator Norton, who we understand gives notice of the introduction of such a bill, will serve the community acceptably by fixing the penalty equal to that of burglary at least. In the enormity of the crimes there is no comparison now as to the severity of the punishment.

THE close of the present volume reminds us of the many obligations we owe to our numerous contributors, friends, and subscribers. We have been much encouraged by their substantial support, and hope to merit them more the coming year. It is but an act of justice to state to our readers that Dr. John Winslow has during the past year prepared the reports from the County Medical Society, and that Dr. Bradford S. Thompson has prepared those from the Academy of Medicine, and has likewise given us valuable aid in the department of Progress of Medical Science. In this latter department Drs. James B. Hunter and A. N. Brockway have rendered us signal service.

Reviews and Notices of Books.

PRACTICAL OBSERVATIONS ON THE ÆTIOLOGY, PATHOLOGY, DIAGNOSIS, AND TREATMENT OF ANAL FISSURE. By WILLIAM BODENHAMER, A.M., M.D. Illustrated by numerous cases and drawings. New York: William Wood & Co., 61 Walker st. 1868.

THE author of this work does not lay claim to any new or startling views regarding the disease of which he treats, but he does claim to furnish the profession with a systematic and practical treatise on the subject. He is of opinion that much is still to be learned in regard to anal fissure, but he endeavors to set forth in as brief a manner as possible all that is known about it at the present time. Hence he has given all the methods of treatment from the earliest times, ending with that which, according to his own experience, he deems best. The first chapter gives a comprehensive review of the history of anal fissure, with a definition of the term, and the means of distinguishing between anal spasm and fissure. In the second chapter the term is more fully defined, and the disease is carefully described. The third chapter takes up the ætiology of fissure; and the fourth gives a classification of the disease according to its anatomical and pathological characters, with its symptoms and means of diagnosis.

The fifth chapter is an excellent résumé of the various methods of treatment, including precautionary and palliative measures. The treatment recommended by the author, and practised by him for twenty-five years, consists, in brief, of topical medication combined with dilatation and sometimes incision or scarification. "The chief indication," he says, "in the treatment of anal fissure, is to modify the surface of the ulcer and transform it into a simple or a common sore, which then, under ordinary circumstances, will heal like any other solution of continuity." As an application, the author has obtained the most uniform and satisfactory results from nitrate of silver, in a solution of one drachm to the ounce. He has also employed *liquor potassæ*, which allays the irritability in an astonishing manner, but does not leave the parts in so favorable a condition for cicatrization as the silver. Where dilatation is necessary he has decided objections to forcible laceration by the thumbs, which operation he considers dangerous and uncertain. In the worst cases he believes it only necessary to incise the mucous membrane and submucous cellular tissue, in order to effect all that is claimed for the more formidable operation of dividing the anal sphincters by stretching or by the knife. On this point, as our readers are aware, there is much difference of opinion among able and experienced surgeons. The experience of Dr. Bodenhamer, who reports in his concluding chapter a large number of cases satisfactorily treated, certainly gives some weight to his opinions in regard to a disease to which he has devoted so much attention.

THE AMERICAN JOURNAL OF OBSTETRICS AND DISEASES OF WOMEN. Edited by DRS. B. F. DAWSON, NOEGGERATH, and A. JACOBI. Vol. I. and II. 1870.

THIS quarterly commenced its first issue in May, 1868, under the auspices of the leading obstetricians of this city, and many other equally eminent specialists abroad. The articles contained in the different numbers have been singularly good and of a thoroughly practical character, a fact which the profession at large have not been slow to appreciate. The care and discrimination of the working editor, who is also the proprietor, Dr. B. F. Dawson, has been one of the principal means to this end. The journal has in the future, as it has had in the past, our best wishes.

ON MORTALITY OF CHILDBED AND MATERNITY HOSPITALS. By J. MATTHEWS DUNCAN, A.M., M.D., L.R.C.S.E., F.R.C.P.E., F.R.S.E., Lecturer on Midwifery and Diseases of Women and Children in Surgeons' Hall Medical School; Clinical Lecturer on Diseases of Women in the Royal Infirmary, &c., &c., &c. N. Y. WM. WOOD & CO.

PROBABLY no living obstetrician is better qualified than Dr. Duncan to prepare a statistical work on the

mortality of child-bed. His own vast experience, both in public and private practice, has afforded him extraordinary opportunities for observation, and he is well known to the profession as an industrious and conscientious compiler of facts. On these facts, in regard to the mortality of child-bed, he bases his arguments upon subjects of controversy concerning hospitals and their management. He claims only that his book is an attempt to arrive at truths, and to use them justly in reaching sound conclusions and overthrowing those that are unsound. His objects in undertaking the work in question were two, one practical and the other scientific. The practical consideration was the defence of hospitals against unjust attacks and misrepresentations. The scientific object was the correction of the statement by Le Fort, that the mortality of women delivered at home is 1 in 212, while that of women delivered in hospitals is 1 in 29.

The author begins by recounting the difficulties in the way of obtaining reliable statistics as to deaths of child-bed, and shows the error that may easily arise from the record of deaths *in* child-bed as deaths *of* child-bed. A case of poisoning by laudanum, for instance, may be a death *in*, but not *of* child-bed. Deaths of child-bed proper he considers those occurring within four weeks from the beginning of labor, exclusive, of course, of those due to causes that would have operated alike if the woman had not been in child-bed. The author places under contribution all the reliable statistics that he can obtain, both of hospitals and of private practice, in all countries and under all circumstances. Many highly interesting facts are thus brought to light, regarding the duration of labor, age, and other conditions in their connection with mortality from puerperal fever. Many of the authorities quoted are allowed to speak for themselves, and the grand results of the author's labor are embodied in tabular form. He finds no ground, he says, for the awful suspicion that well-managed hospitals have caused a large, unnecessary, or avoidable mortality, or developed diseases previously unheard-of. The author, therefore, believes that maternity hospitals should exist, and he gives at some length his opinions as to their construction and management. This is the practical portion of his work, and it should be read and carefully considered by all who are connected with, or interested in, similar establishments. The energy with which Dr. Duncan defends his views is to be accounted for by the fact that he is discussing what has recently been a vexed question in Great Britain, and one that has elicited a general and spirited controversy.

SATAN IN SOCIETY. By a PHYSICIAN. Cincinnati and New York: C. F. Vent; Chicago: J. S. Goodman & Co. 1871.

WE mention this unclean volume only to condemn it in as few words as possible. It is one of those cunningly-devised and mischievous publications that under the guise of virtue and religion parade for the thousandth time the old story of universal masturbation, and attract the curious by disgusting advice about the bridal night, and topics of kindred interest. The writer, whoever he is, may well be ashamed to acknowledge the authorship of such a book, which we sincerely hope, for the good of the public, may prove an utter failure.

THE CAREER OF DENTISTS.—A dentist in Philadelphia has traced out the career of 1,000 dentists, with this result:—163 died before they reached middle life, 643 attained fair success, 57 made fortunes, 27 died from intemperance and other vices, 96 failed entirely, and 3 committed suicide.—*Boston Med. and Surg. Journal.*

Reports of Societies.

NEW YORK MEDICAL JOURNAL ASSOCIATION.

STATED REUNION, NOVEMBER 25, 1870.

DR. ISAAC E. TAYLOR, PRESIDENT, in the Chair.

SYPHILITIC LESIONS OF THE FINGERS AND TOES.

DR. R. W. TAYLOR read a paper upon this subject. He stated that he would treat only cursorily of the lesions of the primary and the secondary period; and he then briefly considered the chief clinical points of the initial lesion as seen upon the fingers; the various forms of secondary lesions of the nails; the appearance of the various syphilides in these localities; and finally he alluded to the occurrence of mucous patches. He desired especially to call attention to a rare form of syphilitic lesion of the fingers and toes, of which there were but five recorded cases, and of which during the past year he had had a case in his service at the New York Dispensary. This lesion, which had been improperly called "syphilitic panaris," was only very meagrely treated of in a few of the text-books, while most of the authors did not mention it. He thought the term *dactylitis*, from δάκτυλος, a digit, more appropriate than "panaris," a synonym of "paronychia, which fails to express the condition."

In this affection the nail is not attacked, but the deeper structures. The lesion is one of the tertiary period, and consists in an infiltration of the gummy material peculiar to that period of syphilis in the subcutaneous connective tissue, in the fibrous structures of the joints, under the synovial membrane, and in the bone. There is also, as a secondary consequence, impaired nutrition of the articular cartilages. An analysis of the recorded cases warrants their division into two varieties: the first variety, that in which there is very considerable deposit in the subcutaneous connective tissue and in the ligaments, and only a moderate amount of it in the bone; the second variety, that in which there is very little, if any, deposit under the integument, while in the deeper structures, particularly the bone, it is very copious.

In the *first variety*, the deposit of gummy material under the integument very much enlarges the digit attacked. The skin generally presents a slight violaceous color. The swelling may extend along the whole length of the finger or toe, or it may involve only a portion; the nail is not affected. It is developed slowly and painlessly, and at the same time a thickening of the capsule of the joint is observed, as well as a slight enlargement of the bone. This bony enlargement in the first variety is not extensive. The ligaments of the phalanx may become very much disorganized; and the mobility of the joint would then be very extensive in all directions, if the deposit in the integument did not give firmness. In all of the recorded cases the lesion of the ligaments has not produced any serious damage of these structures. As a result of the deposit of gummy material in the fibrous structures of the joints, the articular lamella of cartilage undergoes change, which is evidenced by a crepitation heard when the articular surfaces of two phalanges are rubbed together. Since this has never resulted in anchylosis, or disorganization of the joint, it is inferred that the affection of the cartilage is of a slight and transitory character, and due to the impairment of nutrition produced by the deposit in the ligaments from which the cartilage is partly nourished.

The gummy infiltration of the soft parts is commonly absorbed after having existed about six months. It is somewhat singular that in this locality the tendency is to gradual interstitial absorption rather than to degeneration and consequent ulceration. This is attributed to the abundant vascularity of the fingers and toes, and to the more highly cellular character of the gummy material here proliferated. The deposit in the ligaments is also absorbed slowly, and usually leaves them normal; but instances were quoted in which they were left preternaturally lax. The enlargement of the bones also gradually subsides.

The deformities produced by the first variety of dactylitis syphilitica are of two kinds: first, those of the period of progress of the lesion, in which the affected finger or toe is very considerably enlarged, and pushes those on each side of it out of their place; and second, those of the period of decline, in which, owing to slight destruction or absorption of some part of the joint-structures, the finger or toe is left in positions of greater or less superflexion or super-extension.

This first variety, as well as the second, occurs late in syphilis. It is usually a manifestation of profound syphilitic dyscrasia, and coexists with other lesions of a grave character—such as those of the integuments, bone, brain, and viscera. It may occur either in acquired or in hereditary syphilis.

The first variety, then, is characterized by the fact that the deposit is chiefly subtegumentary, involving the connective adipose tissue and not the derma; and while it very extensively involves the ligaments, it only produces slight changes in the bone. But stress was laid upon the fact that in every one of the recorded cases of this variety, the origin of the lesion was recognized early, and proper treatment immediately instituted; and it is difficult to say how far the lesion in the bone would have progressed if not treated thus early.

In the *second variety*, on the contrary, the deposit is chiefly in the bone, and when subtegumentary, which is very rare, it is not copious. In this variety the swelling may commence in an acute manner, involving the whole finger or toe, and then localize itself at one or more of the phalanges, which become very much enlarged out of proportion to the rest of the digit. The disease may attack either the first, second, or third phalanges, one or more of each; those of the fingers or toes alone, or those of both fingers and toes at the same time. Another method of invasion is by a slow, painless enlargement. The swelling in this variety is very great, so that, in one of the cases quoted, a finger at its first phalanx measured about five inches. The lesion here either may begin beneath the periosteum, and then infiltrate the bone, or may begin around the medulla, and from this focus infiltrate the cancellous tissue. In the latter case, this tissue becomes very much swollen, and expands the compact tissue and periosteum, which gradually yield to the pressure and form a wall. The lesions, then, are two, either a syphilitic periostitis or a syphilitic osteomyelitis.

The gummy material thus proliferated may undergo fatty change and interstitial absorption; or it may break down and be extruded. When it does not break down, it produces death of the portion of the bone infiltrated, or, as it is termed by Virchow, dry caries. The infiltrated bone is absorbed coincidently with the absorption of the gummy material, and no lesion of continuity is produced. Thus we may find that nearly a whole phalanx is absorbed without any perforation of the integument; or a part of a phalanx may be absorbed; or the whole phalanx may be much attenuated and shortened. Instances were given in which the middle third of a phalanx was destroyed while the proximal and distal thirds were left intact. In these instances the severed bone was joined together again by a fibrous band, which formed a false joint, very mobile; and, as a consequence, the finger was not responsive to volition. When the gummy material breaks down, it makes its way to the surface, forming a sinus, and escapes as a viscid fluid containing cheese-like flocculi and bony granules. This fluid, when it escapes from a part which has not been irritated, does not contain any pus, but exhibits under the microscope amorphous granular matter, and sometimes connective-tissue cells. Pus is not found in the sinus either, unless it has been irritated. This absence of pus is considered as somewhat diagnostic of syphilitic degenerations. The sinus also presents diagnostic points, as it does not show a tendency to become at its orifice thick, bluish, and everted, as in strumous fistulæ, but generally heals rapidly. One instance was quoted in which a sinus enlarged into an ulcer characteristic of syphilis.

The fibrous structures of the joints are involved in this variety, much as in the first. This variety sometimes presents a hydrarthrosis, which is probably due to deposit in the subsynovial connective tissue. An important symptom of this synovitis is the small amount or entire absence of pain. Though an effusion into the joint has not as yet been observed in the first variety of dactylitis, it was suggested that future observations might perhaps establish the fact of its occurrence.

The articular cartilage is also affected in this variety, the impairment of its nutrition being due to two causes: first, the lesion in the joint-capsule; second, the infiltration in the underlying stratum of bone. As a rule, reparative action begins before very serious disorganization is produced.

The integument suffers only secondarily in this variety. During the period of existence of the lesion, it is much stretched, and its natural folds are effaced; but upon the subsidence of the swelling, it gradually adapts itself again to the diminished size. An interesting case of this adaptation of the integument was related, in which a whole phalanx and part of a metacarpal bone had been destroyed, and yet there was not very much redundancy of skin. This adaptation is beneficial in giving steadiness to the fingers and toes. These lesions run a very chronic course, lasting two or three years, but are amenable to an antisyphilitic treatment.

The deformities are greater and more permanent in the second variety than in the first. In the period of progress, and in the stationary period of the lesion, the fingers and toes are very greatly enlarged and unwieldy, and they distort the adjacent digits. In the final stage the bone may be left either attenuated, or partially or wholly destroyed. It may be left also in a light or fragile condition; or local or general eburnation may be produced. The ligaments generally adapt themselves firmly to the bones, but they may be left very flaccid.

The *diagnosis* is of the utmost importance; for if the syphilitic origin is recognized, an appropriate treatment may be instituted, and will be beneficial; moreover, it will prevent the surgeon from resorting to operative procedures which are unnecessary. The principal affections with which the first variety of dactylitis syphilitica might be confounded are whitlow; gout, when the affection occurs in the great toe; and rheumatoid arthritis, if it attacks many fingers or toes, and especially if it involves the larger joints of the body at the same time. Enchondroma and exostosis also

might possibly be mistaken for this lesion. The second variety of dactylitis is to be diagnosticated from the so-called strumous disease of bone. This latter is prone to attack bones very rich in cancellous tissue; such as those of the carpus and tarsus, and the expanded extremities of the long bones. Besides, in cases of dactylitis a history of syphilis can generally be elicited, or the presence or traces of other syphilitic lesions can be observed.

The *treatment* is that of the tertiary period of syphilis.

STATED REUNION, JANUARY 20, 1871.

DR. S. T. HUBBARD, PRESIDENT, in the Chair.

PNEUMONIA IN ITS RELATION TO OPERATIONS.

DR. H. P. DEWEES presented a paper upon this subject, which he had read at a meeting of the Medico-Chirurgical Society, of this city, nine or ten years before. He wished to claim that date for the ideas advanced in the paper concerning the frequent nervous origin of inflammation and other disorders of nutrition; the frequent development of phthisis as a consequence of pneumonitic processes, or of the introduction of septic matter into the circulation; and the distinction between these forms of phthisis and the tubercular form. The clinical history, pathology, and treatment of pneumonia, both ordinary and secondary to wounds and operations, were discussed at length, the pathology with special reference to the points above named. Our limits preclude any complete analysis of the views expressed, as the paper will probably soon be published; and we simply state the series of questions proposed for further investigation:

"1. What relative frequency exists between operations on the upper and on the lower half of the body, as regards the intercurrence of pneumonia or pleurisy?

"2. After operations, are the upper or the lower lobes of the lungs more subject to inflammation?

"3. Does pleurisy supervene as frequently in intercurrent as in ordinary pneumonia?

"4. Does the side operated upon influence the site of the intercurrent pneumonia; or does double pneumonia occur more frequently when both sides are operated on?

"5. Is gangrene of the lungs a more frequent occurrence in intercurrent than in ordinary pneumonia?

"6. Does abscess occur oftener in traumatic than in ordinary pneumonia?

"7. Is rigor or vomiting as frequent a premonitory symptom in intercurrent as in ordinary pneumonia?"

DR. BUCK was asked to give his experience upon these points, and replied that it was simply negative. He had not observed that operations on the upper extremities differed at all from those on the lower in their liability to be followed by pneumonia; and he had met with nothing upon that point in his reading. He could say the same as to the seat of pneumonia after operations. Gangrene of the lung was an affection of very rare occurrence; and the few cases that he had seen were not connected in any way with wound or operation.

DR. J. C. PETERS thought the pneumonia attributed to operations might often be really chargeable to the exposure of the patient during the operation and in the subsequent dressings. He had observed the case of a woman, who, after an operation upon the right side of the body, did well for two weeks, when suddenly, without apparent cause, she began to be feverish and to be troubled with extreme and persistent nausea. This continued for forty-eight hours. At the end of that time a slight cough led to examination of the chest, which discovered well marked pneumonia in the upper lobe of the right lung. The interesting point in the case was the prolonged and incessant nausea, which had at the time been attributed to a dose of chloral-hydrate administered. Not until the mention of it in Dr. Dewees's paper had the speaker been aware that this was a frequent symptom of the invasion of pneumonia.

DR. DEWEES thought that exposure had commonly less to do with the pneumonia consequent upon operations than had two other conditions—depression of the nervous system, and septicæmia. The incipient stages of pneumonia in these cases were too apt to be overlooked, the patient's condition being attributed by the surgeon to other causes.

DR. WHITEHEAD referred to the frequency of pneumonia, and of metastatic abscesses in the lungs and other organs, after wounds of the head. Dr. Dewees had objected to the use of carbonate of ammonia in pneumonitis, because the blood was commonly overcharged already with ammonia, which the lungs were exhaling, as a rod dipped in muriatic acid and held before the nostrils would show. With reference to this point he would call attention to the striking experience of Dr. Patton in favor of the ammonia-treatment, reported in *Am. Journ. Med. Sci.*, Oct., 1870. In his own hands a combination of chloride of ammonium, chlorate of potassa, and camphor-water, had proved very serviceable.

DR. BURRALL thought Dr. Dewees had too strongly condemned the use of opium in this disease. Judiciously employed, it was often of the greatest value. There was great danger in allowing the patients, when convalescing, to rise too soon, especially aged patients. Cases of sudden death occurred from it.

DR. A. H. SMITH doubted whether, between an injury or operation, and the consequent pneumonia, there was always or commonly the intermediate condition of embolism, or of ichoræmia, which had been referred to. Pneumonia often followed very superficial burns, where neither of these conditions could be supposed to exist. The channel of influence was far more likely to be the nervous system than the circulatory. The pneumonia after injuries often attacked large portions of the lung simultaneously, therein differing from the circumscribed inflammation caused by an embolus. The frequent occurrence of the affection after injuries of the head tended to support the view of its nervous causation.

DR. DEWEES said that the duodenitis long known to result from burns was especially apt to follow those of the parts supplied by nerves from the middle cervical to the second dorsal. He had no doubt that many affections of the abdomen, whether inflammatory, atrophic, or neoplastic, had their origin in the solar plexus.

ANAL SPECULUM.

DR. WHITEHEAD presented a self-retaining bivalve anal speculum, or dilator. The blades were three or four inches long, having bulbous extremities designed to pass just beyond the internal sphincter. From the outer end of either blade, and nearly perpendicular to it, extended an arm, to meet its fellow in a hinge-joint. The arms were separated by a screw. The instrument might be used, if desired, for rupturing the sphincter, though for this the Doctor preferred the fore and middle fingers of each hand. He employed it chiefly to dilate the anus gradually and painlessly, preparatory to the introduction of Sims's duckbill speculum.

DONATIONS TO LIBRARY.

Dr. Peters stated that he had obtained from the "Society Library" a large number of volumes, in exchange for some files of rare old newspapers presented to the Association by Dr. Purdy. On motion, he was authorized to continue his efforts for the increase of the library, which already numbered some two thousand volumes of reference; and donations of books, papers, etc., suitable for the library or for exchange, were solicited.

The meeting adjourned.

NEW YORK MEDICO-LEGAL SOCIETY.

Regular Meeting, January 12, 1871.

Dr. Stephen Rogers, President, in the Chair.

IS CONFESSION EVIDENCE OF GUILT?

Dr. Wm. A. Hammond read a paper upon the *Medico-Legal Value of Confession as an Evidence of Guilt.* The following is an abstract:

It is a very wide-spread opinion that the confession of a person accused of an offence is the best possible evidence of his guilt—an opinion not only entertained by the community at large, but also held by common and statute law, and enforced by numerous judicial decisions. Copious extracts from legal writers were quoted in proof of this statement.

It is now, however, a well recognized principle that a confession, to be of any legal value, must be made without constraint, and without any promise of reward or immunity. But this is a modern refinement. It is not long since supposed criminals were tortured to extort confession; and even now how often do we see a parent or master resorting to torture in one form or other to wring a confession from child or servant.

The existing laws on this subject seem to be based on the principle that a man's eagerness to preserve life, health, liberty, property, is so overpowering that he is not likely, if innocent, to say anything to jeopardize any of these; and that, consequently, if he does confess to any crime whose punishment he knows to be death, mutilation, imprisonment, forfeiture of estate, he must be speaking the truth.

But a glance at criminal history proves it to have been no uncommon thing for persons to confess to offences of which they were either certainly or probably innocent; proves that there are often forces operating in the mind which impel to a false confession, even though life, liberty, or property be thereby endangered. Look at the thousands who, not so long ago, confessed to being witches and holding converse with the devil, although they knew that their confession was consigning them to torture or death. Look at the numbers who, in times of great public excitement about any crime, come forward and proclaim themselves the criminals, when the slightest investigation proves them liars. Look at the numbers who have confessed to crime, for the sake of shielding the really guilty from punishment. Again, look at the cases, so often met with by physicians, where the false confession of some heinous crime is the first observed evidence of mental derangement.

A few years since, a case came before the English courts so remarkable as to justify its discussion here at length. [We have space for only the briefest statement of this case, and of the Doctor's comments, referring the reader, for details, to the paper itself, in the forthcoming (April) number of the *Psychological Journal.*] On the morning of June 30, 1860, Francis Saville Kent, a boy of four years, was found murdered in an out-house on his father's premises. Circumstances made it certain that the murder must have been committed by some member of the household, or by some one secreted in the house before the family retired for the night. The family, including servants, consisted of twelve members. Suspicion fell in turn upon Mr. Kent, the father, Elizabeth Gough, the nurse, and Constance Emily Kent, a daughter of Mr. Kent by a former wife; but, on their examination, no evidence was found against any of them sufficient to warrant commitment for trial. The young lady bore herself remarkably well during the examination, and apparently with the consciousness of perfect innocence. For the two years subsequent to this she went to school, and then, entering a semi-conventual order, remained in seclusion till the spring of 1865, when she voluntarily came forward and declared herself guilty of her brother's murder, and was committed for trial. At the trial she pleaded guilty to the indictment of wilful murder; and on her plea alone, without further evidence, and without the case being sent to the jury, she was sentenced to death.

"Thus, without any inquiry into the character of the influences which had been brought to bear upon her, the tendencies of her disposition while in the religious institution, the sanity or insanity of her mind, her antecedents, or any other point which might have served to throw light upon the case, to lessen her criminality if really guilty, or to weaken the force of her plea if innocent, Constance Kent left the court convicted of the highest crime known to the laws of man. If innocent, her case is one more added to the long list of others—monomaniacs, ecstatics, enthusiasts, hysterical persons, and liars—who have confessed to the commission of offences which they did not perpetrate. If guilty, she is, so far as I know, the solitary instance of an individual confessing to a crime and being sentenced to death upon no other evidence than that admission. Men and women before this, in the face of overwhelming testimony against them, or whilst in a drunken debauch, or on their deathbeds, or standing on the scaffold with no hope of escape, or unintentionally . . . . have confessed their crimes; but if any criminal of sane mind has ever yet voluntarily supplied all the evidence which could consign him or her to an ignominious grave, the case has escaped my observation."

Was she guilty? At the time of the murder she was in her sixteenth year, and had always been accounted a child of sluggish intellect. Her mother had died a lunatic several years before. At the trial she is described as a very plain young woman, with a broad, uninteresting face, expressive of stupid dulness rather than of intelligence, and with none of the shrewd cunning which would seem to have been necessary to commit such a crime and so successfully conceal it. That there was no other evidence of her criminality than her own confession may be fairly assumed from the fact that none was adduced. Had any even suspicious circumstances been discovered, they would not have been allowed to sleep for five years in a community so alert to bring every criminal to justice. During her two years at school, her eccentricity of demeanor was a matter of common remark. During the three years in the *quasi* convent, it is reasonable to suppose that she was subjected to influences calculated to exalt her cerebral sensibility, already abnormal from hereditary predisposition and the terrible experience through which she had passed. She knew that she was suspected. She brooded over the suspicions which had followed the nurse and her

father, driving the one from honest employment, and making the other a broken-hearted and ruined man. She had been taught that self-mortification was the highest privilege of the Christian. Suppose that she had entered the convent fully conscious of innocence; would it be strange if she had finally come to believe herself the murderess, and to think it her duty to relieve those she loved of unjust suspicion by taking the whole guilt upon herself?

It is a matter of daily observation that an idea persistently impressed upon the mind comes at last to be considered as true, no matter how improbable or preposterous it may be. The teller of wonderful stories comes to be unable to distinguish between his experiences and the productions of his imagination. Children often confound their dreams with realities, and are not rarely punished for lying when they fully believe they are relating facts. Hysterical women do the same, as every physician knows.

Mere desire for notoriety will lead men to proclaim themselves gigantic criminals, as in a case which had lately come under the speaker's observation, where a man had persuaded the authorities at Washington that he was a member of a gang of counterfeiters which embraced many most respectable citizens, some of them high in office. On careful cross-examination the man's statements were found contradictory; he was considered subject to a delusion, and was sent to a lunatic asylum. It seemed probable that it was the desire to become notorious which had first undermined his reason. "Do we believe that Father Gaufridi was guilty of bewitching more than a thousand women, and of worshipping the devil, because he confessed these things, and was burned at the stake in expiation of his self-imposed crimes? Do we credit the acknowledgment of Sister Marie de Sains, that she had committed hundreds of murders, strangled numberless children, ravaged graves, breakfasted with devils, and perpetrated thousands of unheard-of sacrileges and barbarities?"

Confession, then, is no sufficient evidence of guilt, and should not be admitted unless confirmed by collateral evidence. Indeed, the legal practice of requiring the accused to plead at all is one that should be abolished.

If the will cannot resist physical torture, and men will confess to anything in order to escape from the present suffering, may we not, in all certainty, apply the same principle to mental torture, or to the overwhelming influence of some ungratified desire, such as may have pressed with resistless force upon the mind of Constance Kent?

But now let us suppose that she did commit the crime, was she fully accountable for it? She was at the most susceptible period of a woman's development, when likes and dislikes are born of the most whimsical fancies, yet often develop a strength beyond the woman's control. We know that even adult men, under a transient attack of cerebral congestion, may become totally transformed, and commit acts which, when the attack is passed, fill them only with horror. At the time of the great change in woman's organism, she is peculiarly liable to derangements of circulation, and specially susceptible to influences that may bring about abnormal cerebral conditions. To hold her accountable for all the results of these conditions is as reasonable and just as it would be to make her responsible for a club-foot or a twisted face. Though the law, instituted for the protection of society, may not recognize this, yet in the interest of strict justice it must be borne in mind, as we may be sure it will be in the Court whose judgment is infallible. If Constance Kent really killed her brother, it must doubtless have been under the impulsion of some such insane condition; and the skill and cunning which enabled her to cover up completely her connection with the deed, and to bear herself so admirably through a searching examination, could hardly have been other than those begotten of (perhaps transient) insanity. Something of the force of these considerations would seem to have impressed the authorities, for her sentence was afterwards commuted to transportation for life.

Mr. Cranfield alluded to a case which happened in Maine some years ago. A man was suddenly missing, and there were strong suspicions of foul play. Two men came forward, confessed to having murdered him, and were about to be hung for it, when their supposed victim turned up alive.

Dr. Miller endorsed the positions taken by Dr. Hammond. One of the things most surprising to the young law-student was to learn the insufficiency of confession, in many cases, as evidence of guilt. It was indispensable that it be made without promise or expectation of reward, or of favor; this was the doctrine now held by the courts. An innocent man is charged with a crime; popular feeling is strongly against him; he is poor, sees all his prospects blighted, and knows not which way to turn. Some friend whispers that if he will only confess, influence may be brought to bear to clear him; and too often he yields to the temptation. There were numerous cases on record of confession simply for the sake of notoriety—for the name of being a great criminal. Every one knew how anxious were the friends of the Artful Dodger that he should have a good record at Newgate. Not less frequent were the instances of confession to save a friend. One was cited in which a man confessed to a murder in order to give the real criminal time to flee the country. When his trial came on he proved an *alibi*. It was very probable that Constance Kent was moved to confession by her sympathies, to restore her father's ruined reputation.

Dr. O'Dea dwelt upon the effect of two principles contending for the mastery in the mind of the criminal—that of self-preservation and that of remorse—the former leading to concealment, the latter to confession. Undoubtedly it was the rule that a murderer's first feeling, after his crime, was fear of the law; and the cases where confession had been instigated by remorse alone were the rare exceptions. Indeed, so firmly implanted was the instinct of self-preservation, that voluntary confession of a capital crime carried on the face of it strong doubt either of the man's truthfulness or of his sanity. The motives prompting to confession were sometimes very curious. It was said that a poor man from the country gave himself up as the murderer of Mr. Nathan, in order to get free transportation to the city, to see his friends—knowing that he could then prove his innocence.

The meeting adjourned.

A New Stethoscope.—Dr. H. J. Wiesel, of Wheeling, Va. (*Pacific Med. and Surg. Journal*), presented to the notice of the West Virginia Medical Society a stethoscope, composed simply of a wooden ovoid cylinder, 1¼ inches deep. One end is covered by a cushion to fit the irregularities of the head, and an elastic band is passed around the forehead to hold it in its place. He claims for it the following advantages: 1st. It is portable; 2d. It does not obstruct the ear; 3d. All mechanical sounds are excluded; 4th. It combines the mediate and immediate methods of auscultation.

New Instruments.

A NEW NEEDLE FOR INTRODUCING THE SUTURES IN RUPTURE OF THE PERINÆUM.

By ALEXANDER J. C. SKENE, M.D.,

PROFESSOR OF DISEASES OF WOMEN AND CLINICAL OBSTETRICS IN THE LONG ISLAND COLLEGE HOSPITAL, BROOKLYN, N. Y.

Rupture of the perinæum has claimed much of my attention, from the fact that cases suffering from this accident are numerous,—much more so than is generally supposed by the profession.

The immediate effects of the injury are so trifling that they are apt to excite but little attention from the physician or patient at the time when it occurs. The trouble usually passes unnoticed until the secondary results, in the form of *prolapsus uteri*, compel the patient to seek relief.

In reviewing my records in the Long Island College Hospital, I find many cases, variously complicated, the report of which could not fail to be of interest to the profession. It was my intention to prepare such report at an early day. But the ground has been recently so thoroughly occupied by an able and exhaustive article on the subject, in the *National Medical Journal*, by Prof. Thompson, of Washington, D. C., that it is only left for me to heartily commend what he has so ably and clearly written.

He has more fully recognized in his excellent article on the subject, not only the frequency of the accident, but the absolute necessity for surgical treatment, than in any paper that has come under my observation; and the history of the many cases he has published shows that his plan of treatment is eminently successful. I have repeatedly practised his method of operating, and can confidently state that it is all that is claimed for it.

His method of operating, I may here state for the benefit of those who have not read the paper, is, in many respects, similar to that of Barker Brown. It differs from it, however, in what I regard as three important points.

1st. He does not divide the sphincter muscle unless the rupture is complete; that is, running through into the rectum; but he paralyzes it by forcible distension.

2d. In place of confining the bowels, which is often difficult during the whole process of healing, he encourages them to move freely, and finds that no evil arises therefrom.

3d. To secure the ends of the deep sutures he uses silver tubes of considerable size, perforated at short intervals, through which he draws the wires, and secures the ends with perforated shot.

This makes a complete operation, every part of which is easily performed, excepting the introduction of the deep sutures; this I have found, I presume in common with other surgeons, often very difficult. I have used the long needle, which is carried in on the left side, curved round, and made to come out on the right, with one sweep; but that is by no means easy to do. I have also used the short needle, carrying it through the left side into the vagina, seizing it there, and bringing it through the right side from within outward; but this also is an awkward manœuvre. By neither of these methods have I been able to get all the stitches exactly as I desired to have them.

Some unusually expert operators may succeed well by either of these methods; but I presume the majority of surgeons have, like myself, found great difficulty in introducing the sutures with accuracy and facility in this way.

With a view to overcoming the obstacles so frequently encountered in the operation, I have devised a needle represented in the accompanying wood-cut. It is about four inches long and slightly curved towards the point. The eye, which is about three-eighths of an inch from the point, has a groove on each side, running longitudinally both ways, and of sufficient depth for the wire to lie in it when being introduced. There is a small notch, cut from the circumference into the eye, large enough to admit a medium-sized silver wire. Through this notch a loop of the wire is carried into the eye, and the ends are pressed into the grooves and carried back through a notch in the handle, which holds them so that the loop cannot slip out of the eye.

The needle thus armed is entered on the left side at the proper distance from the edge of the fissure, and carried through so as to emerge on the vaginal surface. The loop of the double wire is then lifted out of the needle's eye, through the notch, with the tenaculum or finger-nail, and held while the needle is withdrawn. The needle is then introduced, unarmed, on the right side, at a point corresponding exactly to where the wire is located on the other side. The loop of wire projecting on the vaginal surface is then hooked up and carried into the eye of the needle through the notch. The needle is then withdrawn and the wire brought with it. In other words, the double wire is carried through the one side in the same way that the thread is put through cloth by the sewing machine needle, and it is brought out through the other side in the way that a stitch is made with the crochet-needle.

When all the sutures required are introduced, the ends are secured on the right side by passing a piece of gum-elastic catheter through the loops; or, what is better, a piece of hard rubber, oval in shape and notched on the edges at short intervals, into which the loops are carried. The sutures, thus secured at one end, are properly adjusted and tightened, and the loose ends on the left side are brought around another catheter or piece of rubber, and made fast by twisting.

It will be observed that I use *double wire*, believing that it is less liable to cut than the single wire. But the single wire, if preferred, may be used as easily with this needle.

The superficial sutures are introduced in the usual way; but in place of using wire or silk, I employ *horse-hair*, which I consider superior to either of the others, being more easily manipulated than wire, and not liable to cause irritation, even when left in for many days.

The facility with which I have been able to introduce the sutures with this needle in the heretofore rather troublesome operation for *rupture of the perinæum*, has induced me to make it public, believing that others who have met the same inconvenience as myself, will find the instrument both useful and convenient.

Fears were entertained that the notch would catch in the tissues, and thereby obstruct the introduction of the needle, but practically this has not given me any trouble.

Mr. Stohlmann, of the firm of Tiemann & Co., where the instrument was made, suggests that this needle would answer admirably for the operation of cleft palate and similar operations; but as I have no experience in such operations, and do not expect to have any, I shall leave it to others to test its value, if, in their estimation, it possesses any, in this branch of surgery.

Obituary.

PROF. GEORGE THOMSON ELLIOT, M.D., New York.

Dr. George Thomson Elliot was born in the city of New York, May 11, 1827. He graduated at Columbia College in 1845, and immediately began the study of medicine under Dr. Valentine Mott. He attended lectures in the Medical Department of the University of New York, and graduated in the spring of 1849. After six months' service in the New York Hospital he went abroad, and served six months as interne in the Dublin Lying-in Hospital, and seven months as resident pupil in the Dreadnaught hospital ship, London. During a residence of three years abroad he continued the study of medicine in various hospitals of Europe. On his return to New York he passed two years as resident physician in the New York Lying-in Asylum. After leaving the Asylum he at once began practice in New York, in 1853.

Dr. Elliot was appointed physician to Bellevue Hospital in 1854. He was also visiting physician to the N. Y. Lying-in Asylum; visiting and consulting physician to, and one of the founders of, the Nursery and Child's Hospital; for two years he held the position of physician for diseases of the skin and diseases of women and children, at the Northern Dispensary; and he subsequently had the same appointment at the Demilt Dispensary. For one term (1855) he held the position of Professor of Anatomy in the Vermont Medical College, For many years he was assistant to Professor Gilman, in the College of Physicians and Surgeons. Since 1861 he had been Professor of Obstetrics and Diseases of Women and Children in the Bellevue Hospital Medical College, in conjunction with Professors Taylor and Barker.

He was corresponding member of the Edinburgh Obstetrical Society, and of the Royal Academy of Havana. He had also been Secretary and Vice-President of the New York Pathological Society, and was President of the New York County Medical Society at the time of his first apoplectic seizure, June 9th, 1870. At the time of this attack he was attending, in consultation with Professor Thomas and Swift, a bad case of thrombus. When the news spread among his professional friends little hope was entertained in regard to his recovery, and his death was painfully expected day by day. He rallied, however, and was able to spend in comparative comfort, and with many promises of ultimate improvement, several months in retirement at Garrison's on the Hudson.

His ambition for active service in his profession compelled him to return to this city. The excitement incident to this course culminated Jan. 29th in a second attack, the effusion of an immense clot in the ventricles and cord, which terminated in instant death.

It is useless for us to speak of the good qualities of Prof. Elliot as a scholar, a clinical teacher, a lecturer, and a writer. In all these he excelled, blending them in the character of a noble, upright, conscientious man, and a good, faithful, and beloved physician.

WILLIAM BURR BIBBINS, M.D., New York.

Dr. William Burr Bibbins was born in Fairfield, Connecticut, in 1823; graduated at Yale College in 1845, and at the College of Physicians and Surgeons of New York in 1849. He served as House Physician in Bellevue Hospital in 1849, and as Assistant Resident Physician in the Nursery Hospital on Randall's Island in 1850. From 1852 to 1863 he was Visiting Physician to Demilt Dispensary. He was an active member of the N. Y. County and Pathological Societies—Treasurer of both, as well as President of the latter. His death, which was due to typhoid fever, occurred on Jan. 16, 1871.

As a physician Dr. Bibbins was not remarkable for any specially brilliant qualities, but he possessed in a high degree the rarer ones that inevitably command esteem and ensure success. He was an earnest, conscientious toiler in the field of labor he had chosen. He regarded medicine as a sacred calling, and to it he devoted all his energies and all his talents, making the welfare of his patients ever his highest aim. He had the happy faculty of winning and retaining the entire confidence of all who consulted him.

To much professional skill, he united a kind and courteous demeanor alike toward rich and poor, and a genuine practical benevolence that sought to relieve human sorrow in every guise. His life was active, useful, and blameless, and he will long be mourned by a host of friends.

ARMY AND NAVY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from January 4th, 1871, to January 17th, 1871, inclusive.

Mechem, A. F., Surgeon.—By par. 1, S. O. No. 8, Headquarters Department of the Missouri, January 12th, 1871, granted leave of absence for thirty days, on Surgeon's certificate of disability, with permission to go beyond the limits of this Department; and by par. 2, same order, relieved from duty at Fort Hays, Kansas.

Tilton, H. R., Assistant Surgeon.—By S. O. 386, Headquarters of the Army, A. G. O., Dec. 31st, 1870, leave of absence extended sixty days.

Brewer, J. W., Assistant Surgeon.—By S. O. No. 3, Headquarters Department of the Missouri, January 4th, 1871, granted leave of absence for thirty days, on Surgeon's certificate of disability, with permission to go beyond the limits of this Department.

Delany, Alfred, Assistant Surgeon.—By par. 2, S. O. No. 8, Headquarters Department of the Missouri, January 12th, 1871, assigned to duty at Fort Hays, Kansas.

Hall, Jno. D., Assistant Surgeon.—By S. O. No. 2, Headquarters Military Division of the Pacific, January 4th, 1871, granted leave of absence for sixty days, on Surgeon's certificate of disability, with permission to go beyond the limits of the Department in which he is serving.

Bill, Jos. H., Surgeon.—By par. 30, S. O. No. 385, War Department A. G. O., Dec. 31st, 1870, at his own request, under provisions of act of Congress, approved July 15th, 1870, sec. 3, honorably discharged the service of the United States.

Marsh, E. J., Assistant Surgeon.—By par. 28, S. O. No. 385, War Department A. G. O., Dec. 31st, 1870, par. 3, S. O. No. 209, c.s. from A. G. O., accepting his resignation, is revoked; and he is, at his own request,

under provisions of act of Congress, approved July 15th, 1870, sec. 3, honorably discharged the service of the United States, to date Aug. 17th, 1870.

POPE, BENJ. F., Assistant Surgeon.—By par. 30, S. O. No. 385, War Department A. G. O., Dec. 31st, 1870, at his own request, under provisions of act of Congress, approved July 15th, 1870, sec. 3, honorably discharged the service of the United States.

MILLS, M., Surgeon.—By S. O. No. 39, War Dept., A. G. O., Jan'y 28, '71, upon being relieved by Surgeon Perin, to report by letter to the Surgeon-General for assignment to other duty.

PERIN, G., Surgeon.—By S. O. No. 39, War Dept. A. G. O., Jan'y 28, '71, to report to the Com'd'g General, Dept. of the Missouri, for duty as Medical Director of that Department.

MECHEM, A. F., Surgeon.—By. S. O. No. 40, War Dept., A. G. O., Jan'y 28, '71, granted leave of absence for six months on Surgeon's Certificate of Disability.

STORROW, A. S., Asst.-Surgeon.—By S. O. No. 46, Headquarters of the Army, A. G. O., February 1, '71, leave of absence extended thirty days.

PHILLIPS, H. J., Asst.-Surgeon.—By S. O. No. 5, c. s., Headquarters Mil. Div. of the Pacific, granted leave of absence for thirty days.

MIDDLETON, P., Asst.-Surgeon.—By S. O. No. 43, War Dept., A. G. O., Jan'y 31, '71, relieved from duty in Dept. of Arizona, and to report to the Com'd'g General, Dept. of the South, for assignment to duty.

MACKIN, C., Asst.-Surgeon.—By S. O. No. 9, c. s., Headquarters Dept. of the Platte, upon being relieved by Asst.-Surgeon O'Reilly, to proceed to Fort Kearney, Neb., for duty at that post.

O'REILLY, R. M., Asst.-Surgeon.—By S. O. No. 9, c. s., Headquarters Dept. of the Platte, assigned to duty at Sidney Barracks, Neb.

ROSE, GEO. S., Asst.-Surgeon.—By S. O. No. 6, Headquarters Dept. of California, Jan'y 9, '71, relieved from duty at Alcatraz Island, and assigned to Benicia Barracks, Cal.

MICHLER, W. H. H., Asst.-Surgeon.—By S. O. No. 37, War Dept., A. G. O., Jan'y 27, '71, relieved from duty in the Dept. of the Missouri, and ordered to report to the Com'd'g General, Dept. of the Platte, for assignment.

Medical Items and News.

THE NEW JERSEY CITY PATHOLOGICAL SOCIETY was organized at the office of Dr. T. R. Varick, on Wednesday evening, Dec. 28th, 1870.

The Constitution and By-laws adopted are essentially the same as those of the New York Pathological Society.

The stated meetings are to be held at eight P.M., on the second and fourth Thursday of each month, and, for the present, will be at the office of Drs. Watson and Wolfe, 129 Warren street.

The following is a list of the Officers of the Society for the year 1871:

President, Dr. J. E. Culver; *Vice-President*, Dr. M. A. Miller; *Secretary*, Dr. H. S. Gardiner; *Treasurer*, Dr. Henry Mitchell; *Editor*, Dr. Theo. F. Wolfe.

THE DEATH OF PROF. GEO. T. ELLIOT.—At a stated meeting of the New York Academy of Medicine, held February 2, 1871, the following resolutions were unanimously adopted:—

Whereas it has pleased Almighty God, in His infinite wisdom, to remove from us our fellow-member, George T. Elliot, M.D.; therefore, be it

Resolved, That while we bow in submission to the Divine will, we deeply deplore our loss.

Resolved, That in the death of our lamented associate, we recognize the loss of one whose brilliant talents, high moral character, sterling worth, and scientific attainments rendered him an ornament to his profession and to this Society.

Resolved, That we deeply sympathize with the relatives of our deceased brother in their irreparable loss and great affliction.

Resolved, That a copy of these resolutions be published in the Medical Journals of this city, and a copy be transmitted to the family of the deceased.

W. T. WHITE, M.D., Secretary. E. R. PEASLEE, M.D., President.

BELLEVUE HOSPITAL, Feb. 1, 1871.

The Committee appointed to prepare resolutions expressive of the sentiments of the members of the Medical Board of Bellevue Hospital, on the occasion of the death of our associate, the late Dr. George T. Elliot, submit the following:—

Resolved, That in the death of our honored and beloved associate, we have to deplore one who was justly distinguished as a learned, skilful, and accomplished physician, who exemplified an irreproachable life and the virtues of a good citizen; who, in his social relation, was eminently refined, genial, and brilliant, and who was a sincere, devoted, and reliable friend. Removed from us at an age when many more years of active usefulness were to be hoped for, all who have been associated with him will ever hold in cherished remembrance his superior mental endowments, his varied attainments, and the still higher moral qualities which rendered him not less endeared than admired.

Resolved, That as members of this Board, we mourn the loss of a colleague whose counsel and efficient aid in furtherance of the cherished objects of Bellevue Hospital, and in behalf of medical education, have been invaluable, and that, as a slight testimonial of the respect of the Board for his memory, a portrait or bust be procured, to remain permanently in the room in which the meetings of the Board are held.

Resolved, That we tender to the family and relatives our heartfelt sympathy in the bereavement with which an all-wise and beneficent Providence has seen fit to afflict them.

ISAAC E. TAYLOR, M.D., *President*.
A. FLINT, JR., M.D., *Secretary*.

Resolved, That in the death of Dr. Geo. T. Elliot, the Faculty of the College have to deplore the loss of one of the founders of the institution, one who has been connected with it from its inception, and who, by the brilliancy and variety of his talents and attainments, was a main agent in promoting its success and usefulness.

Resolved, That we tender our heartfelt sympathies to the family of our late colleague for the loss of one who was endeared to all by his kindly nature and social qualities, as much as he was respected for his spotless integrity and his high professional skill and acquirements.

B. W. MCCREADY,
AUSTIN FLINT,
AUSTIN FLINT, JR.
Committee.

THE DEATH OF DR. WM. B. BIBBINS.—At a meeting of the Medical Board of the Demilt Dispensary, called for the purpose of giving their united expression in regard to the loss sustained by that institution in the death of Dr. Wm. B. Bibbins, as well as their estimate

of him as a colleague, physician, and citizen, adopted the following preamble and resolutions:—

Whereas, In his infinite wisdom, the Almighty has been pleased to remove from this life our late colleague, and for many years a faithful friend of this Dispensary, Dr. Wm. B. Bibbins;

Resolved, That, as respects the Demilt Dispensary, for whose success he labored in its various departments with unexampled zeal and self-sacrifice, from its foundation to a very recent period, we regard his decease as a very serious loss, for, though not officially connected with it, his mature knowledge of its history and requirements often rendered his counsel desirable and highly valuable.

Resolved, That, as a public-spirited, high-minded, honest physician, his loss to the profession of this city, of the whole State, and, indeed, of the whole country, will be very difficult to repair.

Resolved, That, as a citizen, his active interest in public institutions calculated to advance the welfare of the community, has rendered his loss, at a period of great usefulness, almost a public calamity, while his uniform kindness and very ready charity will, in the language adopted by his esteemed pastor, render him very greatly missed.

Resolved, That, as a citizen, a scrupulously honest officer, a benefactor, and a high-minded, true physician, his removal from us has created a vacancy for which we are not prepared, and which we have little hope of filling.

Resolved, That a copy of these resolutions be transmitted to the Board of Trustees of this Dispensary, to the medical journals of the city, to three of the daily papers, and to the relatives of the deceased.

At the regular meeting of the *Northwestern Medical and Surgical Society*, held at the residence of Dr. Stephen Rogers, on the evening of January 17, 1871, Dr. E. S. Wood, President, in the chair, and Dr. J. C. Thomas, Secretary, after the conclusion of the "Regular Order of Business," the *decease* of Doctor Wm. B. Bibbins was brought to the notice of the Society, and the following "Preamble and Resolutions" were presented by Dr. Ed. C. Harwood, and adopted by the Society, and a copy of the same ordered to be furnished to the medical journals for publication:—

Whereas, We have learned of the death of our professional brother, Dr. Wm. B. Bibbins;

Resolved, That we receive the sad tidings of his death with profound sorrow;

Resolved, That in his death our profession and the community have lost one of its most useful, beneficent, and esteemed members.

Woman's Med. College of N. Y. Infirmary.—At a special meeting of the students, held at the College, Feb. 11, 1871, on the occasion of the death of Mrs. Martha Haines Butt Bennett, the following resolutions were unanimously adopted:—

Whereas, Death has suddenly, and most unexpectedly entered our class, and removed from among us our fellow-student, Mrs. Martha H. B. Bennett, therefore

Resolved, That we gratefully cherish the memory of her warm, generous, impulsive nature, and her ready sympathy for suffering of every kind.

Resolved, that we sincerely regret the untimely death of one to whom life was bright and full of joy, and to whom the future seemed a kind and generous friend, waiting to shower upon her still richer gifts.

Resolved, That we hereby tender our heartfelt sympathy to the bereaved husband, and to the mother so suddenly rendered childless; and the sincere hope that God will comfort them in this great sorrow.

Resolved, That these resolutions be entered upon the minutes of the class, and that the Secretary transmit a copy thereof to the family of the deceased.

Treatment of Wounds by Pneumatic Occlusion.—One of the last numbers of the *Gazette Médicale de Paris* contains a suggestion by M. Guérin for treating wounds by the exclusion of the atmosphere. This is accomplished by placing over the wound a small sac or cylinder of caoutchouc, to the extremity of which a pipe is inserted that is attached to a balloon or chest destitute of air, and which consequently exerts a constant suction power over the seat of injury. By this means, according to M. Guérin, the approximation of the edges of the wound, and their consequent healing by first intention, is facilitated, while it prevents the absorption of pus. By this means, in fact, the wound is placed in the condition of a subcutaneous injury.—*Lancet.*

Rejections at Examinations in Prussia.—In the nine Universities of Prussia, the commissioners examined, for the licence to practise, 434 doctors and candidates in medicine. Out of these 302 were declared fit and proper for practice, hence there were 132 rejections. It should be understood that among the latter there were doctors of medicine, exactly as diplomated candidates for the army and navy are, in this country, sometimes found unfit for a commission.—*Lancet.*

Ophthalmic Surgeons in London.—Most of the ophthalmic talent of London is concentrated at Moorfields Hospital, London. Its list of surgeons includes Messrs. Bowman, Critchett, Hutchinson, Halke, Wordsworth, Streatfield, Lawson, Wells, and Cooper.

Lord Stanley on Health.—In a recent address, Lord Stanley said to some men starting in life:—

"Let them recollect that the race in which they are engaged is one which will last all their working days, and in which endurance is more important than speed. They know already that intemperance is one form of suicide—let them remember that all neglect of physical laws is open to the same reproach, and that there may be intemperance in work as well as in meaner indulgences. You cannot have mental efficiency without health; you cannot maintain health in an exciting and exhausting employment, such as most mental occupations are, when eagerly followed, without some care to preserve it. What I had to tell you about keeping up literary tastes has been said already. They are a great pleasure—a wholesome and a lasting one. Keep them up if you can, and as long as you can. But while you do that, remember also that there is one thing as compared with which not only material health and luxury, but all art, all literature, all science even, are relatively unimportant, and in regard to which the poorest laborer may compete with any of you on equal terms—I mean a steady, untiring performance by each individual of his public and private duty."

English Medical Schools.—The largest London medical schools have the following number of medical students: Guy's Hospital, 304; University College, 207; King's College, 110; and St. Thomas' Hospital, 105. St. Mary's, Westminster, Middlesex, London, and St. George's Hospitals have each less than 100 students. The total number of students in the medical schools, 1309.

The Medical Colleges in New York City.—The medical students now in attendance in the College of Physicians and Surgeons, Bellevue Hospital Medical College, and University of New York, number about nine hundred.

Liver, acute yellow atrophy of, 395.
Lithotripsy, clinical lecture on, 342.
Localized movements, 270.
Liver, seat of urea, 441.
Loines, Dr. J. P., vaccination, 525.

Sphygmograph, availability of the, 9.
Spleen, rupture of, 212; cancer of, 196.
Stethoscopes and their uses, 234.
Stone, anomalous cases of, 232.
Strictures of urethra, lectures on, diagnosis and treatment of, 29, 54, 73, 101.
Stomach, perforating ulcer of, 41.
Strong drink, notice of work on, 352.
Strychnine as antidote to chloral, 107.
Stumps, a dressing for, 402.
Style, a new lachrymal, 119.
Sudden death, cardiac disease, 39, 135.
Sulpho-carbolate of potash in croup, 53.
Syphilis, origin in Europe, 23.
Syphilis of nervous system, 404; of fingers and toes, 568.
Syphilization, remarks on, 331.
Syphilography, American Journal of, 182.

T.

Tænia, large doses of turpentine in, 423.
Tanner, Dr. T. H., notice of works by, 39, 326.
Tapeworm, turpentine in, 423.
Taylor, Dr. C. F., localized movements, 270.
Tea culture in Tennessee, 120.
Temperature, post-mortem elevation of, 240; of children in tuberculosis, 107.
Terry, Dr. C. C., sulpho-carbolate of potash, etc., in croup, 53; ligation of external iliac, 224.
Testicles, cancerous, weighing five pounds, 12.
Tetanus, large doses of opium in, 440.
Thermometer, a surface (illustrated), 503.
The *Practitioner*, notice of the, 495.
Thrombus of right subclavian, etc., 39.
Thrombosis of portal vein, 88.
Thomson, Dr. W. H., cancer of mesentery, 449; classification of remedies, 531.
Thompson, Dr. Bradford S., medical recollections of England in 1868, 113; reports from, 210, 374.
Throat, simple method of examining, 179.
Tillou, Francis, Esq., sale of poisons, 317.
Tobacco, notice of work on, 352.
Toe, torn out by root, 423; new treatment for ingrowing nail of (illustrated), 196.
Tongue, congenital hypertrophy of, 483.
Tongue, coating of the, 357; leaden color of in malaria, 106.
Townsend, Dr. T. B., amputation of hip, 415.
Trachea, hair-pin in the, 18.
Transfusion, successful case of (illustrated), 21, 120; new method for, 131.
Trismus nascentium, cases of, 248.
Trueheart, Dr. C. W., ingrowing toe-nail, 196.
Tuberculosis, remarks on, 95, 107, 136, 173, 258, 424, 457, 496, 505.
Turpentine, large doses of in tape-worm, 423.
Tympanitis, ice poultices in, 159.
Typhoid fever, death from on fiftieth day, 21; treatment of, 250.

U.

Uræmia, large doses of calomel in, 413.
Urea in liver, 441, 537; in urine and nervous symptoms, 375.
Urethra, lectures on, diagnosis and treatment of, 29, 54, 73, 101; chronic discharges of, 252; morbid sympathies of the, 188, 237.
Uric acid diathesis as a cause of Bright's disease, 106.
Urine in muscular exercise, 376.
Uterine hemorrhage, Barnes on, 10; medication, 183; concealed hemorrhage, 448, 512.
Uterus, new sound for (illustrated), 356; muscular labor of, 202; recovery from rupture of, 23.

V.

Vagina, senile, contraction of, 418.
Van Geison, R. E., cancerous tumor, 473; detached placenta, 473; degeneration of ovum, 403.
Van Graefe, death of, 285.
Veratrin, action of, 11; venesection in obstetrics, 510.
Veratrum viride *vs.* opium, 467; in children's diseases, 291; overdose of, 472; in convulsions, 551.
Vermilion, to preserve color of, 142.
Virchow as a statesman, 383.
Vision of animals, 142.
Vogel, Dr. A., notice of a work by, 16.
Vulva, thrombus of, 294.

W.

War of rebellion, surgical memoirs of, notice of, 302.
Water, cold, febrifuge action of, 392.
Watts, Dr. Robert, multiple tumors, 63.
Weir, Dr. R. F., sub-periosteal effusion, etc., 163.
Welch, Prof. G., review of work by, 14.
Whitehead, Dr. W. R., reproduction of bone, 112.
Whooping-cough, belladonna in, 17.
Woodward, J. J., U. S. A., on certain points connected with the histology of minute blood-vessels, 313.

Y.

Yale College, surviving graduates of, 335.
Yellow fever and Health Board, 397.

CONTENTS OF VOLUME V.

A.

Acupressure, hemorrhage after, 65.
Acupuncture, 201.
Adirondack mineral spring, observations on, 33.
Agnew, Dr. C. R., treatment of lachrymal diseases, 366.
Albumen, practical value of new tests for, 319.
Allen, Dr. Nathan, review of work by, 14.
Althaus, Dr. Julius, review of work by, 231.
Air-passages, foreign bodies in, 278.
Ambrose, Dr. D. R., pin in walls of heart, 83.
American Medical Association, meetings of, 121, 133; transactions of the, notice of, 495.
American medical journalism, on, 253, 349.
American Pharmaceutical Association, 130.
Amputations—in Pennsylvania Hospital, 491; spontaneous in utero, 419.
Aneurism, without dilatation, 449; ergotin in, 544.
Anæsthetic, a mechanical, 515.
Antero-posterior symmetry, articles on, by Elliott Coues, M.D., etc., 149, 193, 222, 272, 297, 370, 390, 438.
Antiphlogistic treatment in diseases of children, 97, 245, 289, 305, 337, 354, 361.
Antiseptic, a new, 384.
Aphthæ, treatment of, 161.
Aortic disease and Bright's kidney, 197.
Apoplexy, meningeal, the cause of death in the new-born, 20; diagnosis of, 356.
Appendix vermiformis, inflammation of, 18; inflammation of, without perforation, 19.
Army and navy news, 430, 453, 504, 524, 574.
Army medical service abroad, 301, 429.
Asthma, a remedy for, 466.
Asylums, insane, reports of, 111.
Atomizer, new glass (illustrated), 237.
Atrophine *vs.* opium, 166.
Aural patients, examination of, 385.
Autopsy, how soon should it be made, 424
Auzias-Turenne, death of, 238.
Axe, fragment of, passed per rectum, 468.

B.

Bailey, Dr. James S., on regimen as a prophylactic, 177; trismus nascentium, 248.
Barker, Dr. B. F., thrombus of vulva, 294; bloodletting, 510, 520.
Barker, Dr. G. F., notice of work by, 537.
Barnes, Dr. Robert, notice of work by, 206.
Bartholow, Dr. R., notice of work by, 15; letter from, 327.
Beard, Dr. G. M., electro-surgery, 486; galvanic apparatus (illustrated), 329.
Bedford, Dr. G. S., death of, 330.
Beef-tea, mode of preparing, 249.
Beekman, Dr. John N., dislocation of head of radius, 392.
Belladonna, history and uses of, 78
Bellevue and Charity Hospital reports, notice of, 16.
Bell, Dr. John, on Adirondack mineral spring, 33.
Bennett, Dr. E. P., delirium tremens, 83; hydrocele in female, 415.
Bibbins, Dr. W. B., death of, 552, 574.
Biddle, Dr. J. J., notice of work by, 537.
Bill, Dr. J. H., a new hypodermic syringe (illustrated), 45.
Bladder, absorbent power of the, 419; new method of puncturing, 117.
Blepharoplasty, case of, 452.
Bliss, Dr. Chas. A., new lachrymal, 119; style bloodletting in obstetric practice, 510, 520.
Blood-vessels, certain points connected with histology of, 313.
Bone, formation of in the eye, 402; reproduction of, 112, 358.
Boston City Hospital, report, notice of, 536.
Bright's disease, lime-water in, 11; retinal changes in, 490.
Bromide of potassium in leucorrhœa, 466; for children, 180, 467.
Broncho-pneumonia, latent, 41.
Brown, Dr. Paul R., medullary cancer, spleen, 196.
Buck, Dr. Gurdon, congenital hypertrophy of tongue (illustrated), 483; puncturing bladder, 117; tracheotomy, etc., 278; closing of nasal fossa (illustrated), 535.
Burns, white-lead dressing in, 143.
Bumstead, Dr. F. J., notice of work by, 519.
Buttocks, firmness of in infants a sign of health, 166.
Byford, Dr. W. H., review of work by, 303.

C.

Calculus, largest on record, 311.
Calomel, large doses in uræmia, 413.
Cammann's stethoscope, improvement of, 44.
Canada Medical Association, report of, 353.
Cash payments for medical services, article on, by editor, 37.
Casts, fibrinous, from iodide potassium, 405.
Cancer, can it disappear spontaneously, 63.
Cancers treated by electrolysis, 355.
Capillary circulation, vibration as a mechanical influence in promoting, 416.
Carbonate of soda of Bible, 495.
Cataract, modified linear extraction in, 12.
Cell doctrine, the, notice of work on, 470.
Cement, a firm, 95.
Cerebro-spinal sclerosic palsy, 265.
Chalk mixture, formula for, 442.
Chamberlain, W. M., tuberculosis, 463.
Chancres, a dressing for, 35.
Child, sex of, influence of in parturition, 358.
Children, antiphlogistic treatment in diseases of, 97, 245, 289, 337, 361.
Chinese therapeutics, 141.
Chloral, remarks on, 94, 107, 159, 197, 225, 226, 228, 284, 324, 332, 490, 514.
Chloroform, ice in accidents from, 107; new vehicle for, 137; in parturition, 394.
Choroid, ossification of, 449.
Circulation, capillary, vibration as promoting, 416.
Circumcision *vs.* epilepsy, 233.
Clark, Dr. Alonzo, lectures on relapsing fever, 1, 25, 69.
Clark, C. C. P., Dr., treatment of phlegmasia dolens with opium, 155.
Clark, Sir James, death of, 238.
Clavicle, fracture of sternal extremity of, 417.
Clymer, Dr. Meredith, lectures on "the palsies and kindred disorders of nervous system," 145, 169, 217, 241, 265, 339; epileptics, mental state of, 363, 409.
Cockleburr as a styptic, 394.
Cod-liver oil, bismuth to aid in the digestion of, 201.
Cooper, Sir A., Dr., income of, 139.
Copland, Dr. James, death of, 310.
Copper *vs.* cholera, 11.
Confession as an evidence of guilt, 571.
Conjugal Onanism, notice of work on, 182.
Constipation in infants, 160.
Consultations, ethics of, 445.
Controversial pamphleteering, 277.
Corelysis, new method of, 490.
Corns, radical cure of, 179.
Coues, Dr. Elliott, antero-posterior symmetry, with special reference to the muscles of the limbs, 149, 193, 222, 272, 297, 370, 390, 438.
Cranial cavity, temperature of, 276.
Croup, solvents for membranes of, 53.

D.

Damon, Dr. H. F., notice of work by, 88.
Death, sudden, with insignificant lesions, 20.

Delafield, Dr. F., invagination in camel, 65; idiopathic croupous inflammation of stomach, 65.
Delirium tremens, remarks on, 83, 329.
Detmold, Dr. W., anomalous cases of stone, 232.
Diabetes, opium in, 250; origin of, 203, 207.
Diet in children's diseases, 363.
Digitalis in infantile diseases, 291.
Diphtheria, balsam and cubebs in, 191.
Durham's, tracheal canula (illustrated), 453.
Draper, Dr. W. H., on pulmonary phthisis, 399, 459; casts in urine from iodide potash, 405.
Dyspepsia, infantile, nourishment in, 168.

E.

Eager, Dr., inflammation of appendix vermiformis, 18.
Ear, middle, the mastoid process in inflammatory affections of, 433; diseases of, 159.
Echinococci of liver removed by operation, 283.
Eczema, pathology of, 42.
Editorial articles, 13, 37, 61, 85, 109, 133, 157, 181, 205, 229, 253, 277, 301, 325, 349, 373, 397, 421, 445, 493, 517, 541, 565.
Education, medical, present aspect of, 229; preliminary editorial remarks on, 421.
Electricity in diseases of children, 362; in obstetrics, 107.
Electro-surgery, present state of, 486.
Electrolysis, erectile tumor cured by, 464; in malignant tumors, 355.
Elliot, Dr. Geo. T., antiphlogistic treatment of children, 305; letter from, 449; death of, 574.
Epileptics, lecture on the mental state of, 363, 409.
Epsom salts, masking the taste of, 199.
Epithelioma, lip, in patient aged 21, 475; of penis, 403.
Ergot, uses of, 34, 60, 307, 544.
Ether drunkenness in Ireland, 120.
Ethics of consultations, 445.
External iliac, ligation of, 224.
Eye, formation of bone in the, 402, 529.

F.

Face presentation, remarks on, 35.
Fallopian pregnancy, case of, 251.
Female physicians, shall we consult with, 205.
Femoral artery, superficial incised wound of, 105.
Femur, spontaneous discharge of head of, 118.
Fever, in children, treatment of, 97.
Fibro-myoma uteri, treated by electrolysis, 89.
Fibroma uteri, 231.
Finnell, Dr. T. C., pathological specimens by, 20, 39, 62, 135, 352, 402, 422, 448, 472.
Flatus, chronic, death from, 353.
Flint, Dr. A., chronic diseases of heart, 66; diabetes, 207; tuberculosis, 424, 496; muscular exercise, 164, 376.
Flint, Dr. A., Jr., diabetes, 208; notice of work by, 86.
Food for infants, time to give, 492.
Forceps, use of in labor, 216.
Fowler, W. H., notice of work by, 519.
Freeman, Dr., turpentine for tapeworm, 423.

G.

Galvanic apparatus (illustrated), 329.
Galvanic and Faradic currents, comparative value of, 152.
Gay, C. C. F., radical cure of hernia, 485.
Glycerine adhesive plaster, 43.
Goitre, exophthalmic, with insanity, 332.
Gonorrhœa, treatment of, 179.
Gonorrhœa, tannin and glycerine in, 466.
Gouley, Dr. J. W. S., strictures of the urethra, 29, 54, 73, 101; on lithotripsy, 342.

H.

Halsted, Dr. Thaddeus M., notice of death of, 407.
Hair-pin, removal of from uterus, 36.
Hare-lip, a new method for treating, 417.
Hamilton, Dr. F. H., letter from, 43.
Hart, Dr., fibroma uteri, 232.
Harvey, Dr. P. F., delirium tremens, 328.
Health Board, vagaries of, 397.
Health law, remarks on, by editor, 85.
Heart, bullet wounds of, and recovery, 232; first sound of, 202; disease of, a cause of death, 116; hypertrophy of, 62; labor of, 335; rupture of, 210; pin in walls of, 83; prognosis of disease of, 66, 92; clots, frequency of, 108.
Hematoma auris, remarks on, 418.
Hemoptysis, ipecac in, 10.
Hemorrhoids, treatment of, 562.
Hereditary influences, 96.
Herniotomy, 144.
Hernia, radical cure of, 485.
Hewitt, Dr. H. S., incised wound of superficial femoral, 105.
Hiccough, musk in, 167.
Hip-joint, amputation at, 415.
Holden, Dr. E., on a new sphygmograph (illustrated), 9.
Humerus, dislocation of from sneezing, 286.
Hunter, Dr. J. B., a holder for Sims' speculum, 431.
Hunt's cement, 527.
Hutchinson, Dr. J. C., hemorrhage after acupressure, 65; epithelioma of penis, 403; work by, 422; morbus coxarius, 162.
Hydrocele in a female, 415.
Hydropneumo-thorax, 134.
Hypodermic syringe, a new, 45.

I.

Indigestion, acute, treatment of, 299.
Infantile constipation, 160.
Insane hospitals, notices of reports of, 111.
Intermarriage of relations and the laws of human increase, 14.
Intermittent chills, disease of spleen as a cause of, 196.
Intussusception the primary or secondary cause of death, 183.
Iodide of potassium causing casts in urine, 405.
Iodine in diseases of children, 361.
Iodized milk, 467.
Influenza, a remedy for, 374.
Intermittent fever, notes on, 391.
Iron cottage hospital, an, 375.

J.

Jacobi, Dr. A., antiphlogistic treatment in diseases of children, 97, 245, 289, 337, 361; address of, 450; echinococcus, 283.
Janeway, Dr. E. G., perforation of stomach, 41; thrombosis of portal vein, 88; aneurism without dilatation, 449.
Johnston, Dr. Christopher, a new canula (illustrated), 453.
Journal of the Gynæcological Society of Boston, notice of, 62.

K.

Keyes, Dr. E. L., syphilis of nervous system, 404.
Kidder, Dr. J. C., notice of work by, 88.
Kidney, bloody cyst under capsule of, 135; extirpation of, 93.
Kilbourne, Dr. H. S., intermittent fever, 391.
King, A. F. A., Dr., on capillary forces, 416.
Kings County Hospital, report from, 372.
Knapp, Dr. H., formation of bone in the eye, 402, 449, 529; blepharoplasty, 452.
Knife-blade coughed up, 397.

L.

Labial hematocele, 329.
Labio-glosso-laryngeal palsy, 339.
Lachrymal diseases, the treatment of, 366, 377.
Laminaria tents, 539.
Leaming, Dr. J. R., tuberculosis, 462.
Lee, Dr. C. C., relapsing fever, 91; pericarditis, 91.
Leucorrhœa, bromide potassium in, 466.
Lewis, Dr. W. B., relapsing fever, 212; tests for albumen, 319.
Lincoln, R. P., local medication of air-passages, 476; electrolysis in erectile tumor, 464.
Lip, lower, peculiar inflammation of, 442.

THE MEDICAL RECORD.

A Semi-Monthly Journal of Medicine and Surgery.

No. 120.

Vol. 5. No. 24. Whole No. 120. | NEW YORK, FEBRUARY 15, 1871. | $4.00 Per Annum.

Subscribers will please find enclosed bill for Vol 6.

No. 121 will commence a new Volume.

CONTENTS.

Medical Society of the State of New York:

The President's Inaugural Address—Miscellaneous Business—The Presentation of Papers—Puerperal Eclampsia—Permanent Members from different Districts, 558; Prize Essays—A Charge of Plagiarism—Urethrocele, Catarrh, and Ulceration of Female Bladder, 554; Permanent Members from different Districts—Astigmatism and other Defects of Sight from Abnormal Refraction—Another Protest from the Country Members—Reports of Delegates—The Protection of Foundlings, 555; Concerning Permanent Members—On By-Laws—Divergent Squint—A New Jointed Silver Catheter—A Flexible Silver Bone Probe—Anæsthesia and a New Instrument, 556; Artery Constrictor—The Case of Dr. Thoms—Dr. Sayre and his Malpractice Suit, 557; Committee on Psychology—On the Work at Surgeon-General's Office—Report of Committee on Nominations, 558; Concerning Careless Pharmacy, etc., 559; The Niagara County Society—Costs in Malpractice 560

Progress of Medical Science:

Pepsin and its Medicinal Preparations, 560; The Constricting Silver Ligature in Aneurism—Topical Medication in the Treatment of Endo-Metritis—Liquid for the Preservation of Wet Anatomical Preparations—Malignant Tumors, 561; The Seat of Tumors—Treatment of Hemorrhoids—Carbolic Acid in Carbuncle—The Administration of Chloral—A Case of Foreign Body in the Trachea—Sulpho-Carbolate of Zinc—Strangulated Hernia—Speedy and Spontaneous Recovery from Rupture of Rectum and Bladder—Varicose Veins, 562; Stricture of the Urethra—Hydrate of Chloral in the Treatment of Congestion of the Retina—Radical Cure of Artificial Anus—Case of Extra-Uterine Pregnancy—Chloroform in the Treatment of Biliary Calculi—Treatment of Irritable Heart—Acute Atrophy of the Liver—Fibrous Tumors on the Lobes of the Ears—The Value of Emetics, 563; Treatment of Chronic Hydrocephalus—Median Lithotomy—Modern Surgery—The Use of Unctuous Substances in the Lying-in Chamber—Abscess within the Cranium—Asthma—Fracture of Neck of Femur, with Inverted Foot—Skin-Grafting Superseded—Aloin—The Removal of External Hemorrhoids 564

Editorial:

THE PROCEEDINGS OF THE STATE MEDICAL SOCIETY 565
CONVICTION OF ABORTIONISTS 566

Reviews and Notices of Books:

Practical Observations on the Ætiology, Pathology, Diagnosis, and Treatment of Anal Fissure. By William Bodenhamer, A.M., M.D. 557
The American Journal of Obstetrics and Diseases of Women. Edited by Drs. B. F. Dawson, Noeggerath, and A. Jacobi ... 567
On Mortality of Childbed and Maternity Hospitals. By J. Matthew Duncan, A.M., M.D., L.R.C.P.E., F.R.C.P.E., F.R.S.E. 567
Satan in Society. By a Physician 568

Reports of Societies:

NEW YORK MEDICAL JOURNAL ASSOCIATION.—Syphilitic Lesions of the Fingers and Toes, 568; Pneumonia in its Relation to Operations—Anal Speculum, 570; Donations to Library 571
NEW YORK MEDICO-LEGAL SOCIETY.—Is Confession Evidence of Guilt? 571

New Instruments:

A New Needle for Introducing the Sutures in Rupture of the Perinæum. By Alexander J. C. Skene, M.D. 573

Obituary:

Prof. George Thomson Elliot, M.D., New York 574
William Burr Bibbins, M.D., New York 574
Army and Navy News 574

Medical Items and News:

The New Jersey City Pathological Society—The Death of Prof. George T. Elliot—The Death of Dr. William B. Bibbins, 575; Woman's Medical College of New York Infirmary—Treatment of Wounds by Pneumatic Occlusion—Rejections at Examinations in Prussia—Ophthalmic Surgeons in London—Lord Stanley on Health—English Medical Schools—The Medical Colleges in New York City 576

Announcements of New Books in Press.

WILLIAM WOOD & CO. take pleasure in announcing that they propose to begin the publication, in the summer or autumn of this year, in a series of monthly numbers, by subscription, of

A DICTIONARY OF MEDICINE AND SURGERY,

BY A CORPS OF EMINENT PHYSICIANS AND SURGEONS,

On the basis of **Nysten's DICTIONNAIRE DE MEDECINE** (edition of 1870).

IN ONE IMPERIAL OCTAVO VOLUME. PROFUSELY ILLUSTRATED WITH WOOD ENGRAVINGS.

BY SPECIAL ARRANGEMENT WITH THE ENGLISH PUBLISHERS.

IN PREPARATION,

IN THREE VOLUMES OCTAVO,

THE WORKS OF SIR J. Y. SIMPSON, Bart.

VOL. I.—SELECT OBSTETRIC AND GYNÆCOLOGICAL WORKS.

Edited by **J. WATT BLACK, M.A., M.D.**, Physician-Accoucheur and Lecturer on Midwifery and Diseases of Women and Children to Charing Cross Hospital, London, formerly Assistant to the late Sir James Simpson.

VOL. II.—ANÆSTHESIA, HOSPITALISM, &c., &c.

Edited by **Sir WALTER SIMPSON, Bart.**

VOL. III.—THE DISEASES OF WOMEN.

Edited by **ALEXANDER SIMPSON, M.D.**, Professor of Midwifery in the University of Edinburgh.

WM. WOOD & CO., Publishers.

COLLEGE OF PHYSICIANS AND SURGEONS,

Corner of Twenty-third Street and Fourth Avenue, New York.

SIXTY-FIFTH SESSION.

1871–72.

FACULTY OF MEDICINE.

EDWARD DELAFIELD, M.D., President, and Professor Emeritus.
WILLARD PARKER, M.D., Professor of Clinical Surgery.
THOMAS M. MARKOE, M.D., Professor of Surgery.
ALONZO CLARK, M.D., Professor of Pathology and Practical Medicine.
JOHN T. METCALFE, M.D., Professor of Clinical Medicine.
JOHN C. DALTON, M.D., Professor of Physiology and Hygiene.
SAMUEL ST. JOHN, M.D., Professor of Chemistry.
T. GAILLARD THOMAS, M.D., Professor of Obstetrics and the Diseases of Women and Children.
HENRY B. SANDS, M.D., Professor of Anatomy.
FREEMAN J. BUMSTEAD, M.D., Clinical Professor of Venereal Diseases.
JAMES W. McLANE, M.D., Professor of Materia Medica, Therapeutics and Medical Jurisprudence.
THOMAS T. SABINE, M.D., Adjunct Lecturer on Anatomy.
WILLIAM H. DRAPER, M.D., Clinical Professor of Diseases of the Skin.
CORNELIUS R. AGNEW, M.D., Clinical Professor of Diseases of the Eye and Ear.
ABRAHAM JACOBI, M.D., Clinical Professor of Diseases of Children.
THOMAS T. SABINE, M.D., Demonstrator of Anatomy.
JOHN G. CURTIS, M.D., Assistant Demonstrator.

IN THE PLAN OF INSTRUCTION adopted in this Institution, Clinical Teaching constitutes an important and prominent feature, all the practical subjects treated of in the Didactic Course being fully illustrated at the bedside. In the furtherance of this object, the extensive Hospitals of New York, of which the New York Hospital, the Bellevue Hospital, the Charity Hospital, Blackwell's Island, and the New York Eye Infirmary are the largest and most efficient, furnish ample fields for instruction and study.

To all of these the Faculty of the College resort for the purposes of practical instruction, Cliniques being held daily in one or more of them.

Besides the Clinical Lectures given at the Hospitals, there are eight Cliniques each week at the College Building, viz.:

Surgical Clinique, by Prof. PARKER, every Monday at 12 M.
Medical Clinique, by Prof. CLARK, every Thursday at 12 M.

SUMMER SESSION.

FACULTY.

FESSENDEN N. OTIS, M.D., Lecturer on Diseases of the Genito-Urinary Organs.
A. BRAYTON BALL, M.D., Lecturer on Diseases of the Kidneys.
JAMES L. LITTLE, M.D., Lecturer on Operative Surgery and Surgical Dressings.
EDWARD C. SEGUIN, M.D., Lecturer on Diseases of the Nervous System.
GEORGE G. WHEELOCK, M.D., Lecturer on Physical Diagnosis.
WOOLSEY JOHNSON, M.D., Lecturer on Diseases of the Larynx and Laryngoscopy.

The Summer Session for 1871 will commence on Monday, March 13th, and will continue three months. Two Didactic Lectures will be given daily during this course, and the College Cliniques held as usual.

Instruction in Practical Chemistry will be given in the Laboratory under the direction of Professor ST. JOHN, to those who wish to make themselves personally familiar with the more important manipulations in chemical analysis.

Instruction will also be given in Physical Diagnosis and Practical Laryngoscopy, and obstetrical cases furnished to the class. No additional charge will be made, for the above, to students who take the General Ticket for the Summer Session.

Certificates of attendance on this course will be counted as time spent in the study of medicine under the direction of a practitioner.

Matriculation Fee, $5; valid for the year. General Ticket to all the Lectures, $30. For each separate ticket, $5.

REGULAR SESSION.

The Regular Course of Lectures for the Session of 1871–72 will commence on Monday, the second day of October, 1871, and will continue until the following March. This course will consist of from five to six Daily Lectures in the various departments of Medicine and Surgery, both elementary and practical, together with Daily Clinical Lectures, delivered both at the College and at the larger Hospitals.

Matriculation Fee, $5; Fees for the full Course of Lectures by all the Professors, $140; for each separate ticket, $20; ticket of the Demonstrator of Anatomy, $10; Graduation Fee, $30.

The Tickets are to be taken at the beginning of the Session.

Students who have attended two full courses in this College, or who, having attended one full course in some regularly established medical school, shall *subsequently* attend one full course in this College, are admitted to a third course of lectures on paying the matriculation fee only.

Graduates of this school are admitted without fee. Graduates of other regular schools, who have been in practice three years, and *Theological Students*, are admitted on general ticket by paying the matriculation fee.

Recent Graduates of other regular schools, and students who have already attended two full Courses of Lectures, are admitted to this College on payment of the matriculation fee and $70.

Students are requested, on their arrival in this city, to call at the College and register their names with the Clerk, Mr. Boag, who will give them all necessary information, and aid them in obtaining board.

For the Annual Catalogue, and further information, address the Secretary of the Faculty, *JAMES W. McLANE, M.D.*, College of Physicians and Surgeons, corner of 23d Street and 4th Avenue, New York.

GELATINE-COATED PILLS.

The coating of Pharmaceutical Pills with Gelatine has been known for some time and recommended in several pharmaceutical journals, though the process, that of coating each pill separately, was too slow and laborious to admit of general use. By the employment of machinery, invented and patented by a Frenchman, we are now enabled to offer the gelatine-coated pills at a trifling advance on the price of sugar-coated, the advance being due to the difference of labor between the two processes.

Physicians need only to see these pills, to indorse their superiority over the sugar-coated on account of reliability and solubility. Sugar is often distasteful to the stomach, and sugar-coated pills have often been known to pass through the intestinal canal unchanged.

Samples and Circulars forwarded upon application.

FLUID EXTRACTS. (By cold percolation.) **AROMATIC ELIXIRS.** (With formulas attached.) **PURE COD-LIVER OIL.**

McKESSON & ROBBINS,

W. R. GILLETTE, M.D., Lecturer on Venereal Disease.

JOSEPH W. HOWE, M.D., Lecturer on Surgery.

G. ECHEVERRIA, M.D., Clinical Professor of Diseases of the Mind and Nervous System.

L. ELSBERG, M.D., Clinical Professor of Diseases of the Throat.

H. S. HEWIT, M.D., Clinical Lecturer on Surgery.

WM. B. LEWIS, M.D., Lecturer on Diseases of the Kidney.

JAS. F. FEELEY, M.D., Demonstrator of Anatomy.

THE COLLEGIATE YEAR is divided into two Sessions—a regular Winter Session, and a Spring, Summer, and Autumn Session. The latter is auxiliary to the former, and the design of the Faculty is to furnish instruction to medical students throughout the year. *Attendance on the regular Winter Session is all that is demanded of the candidates for graduation.* Those who attend the other session receive a CERTIFICATE OF HONOR, as having pursued voluntarily a fuller course than usual.

THE SPRING AND SUMMER SESSION is principally of a practical and clinical character, and affords particular facilities to students who have already taken one course in schools where such practical advantages exist to a less extent. The course consists also partly of lectures and examinations on the subjects necessary for graduating in medicine, conducted by the Professors of the regular Faculty and their assistants. These examinations will be addressed to both first and second course students.

For the purpose of making the visits to the wards of the hospitals as available as possible, the class is divided into sections. One division at a time is instructed in practical Diagnosis, Prescription, and Treatment of Patients. The course begins in the middle of March, and continues till the beginning of June, when the SUMMER COMMENCEMENT is held. During the Summer the College Clinics are kept open.

THE AUTUMN OR PRELIMINARY SESSION commences on the first of September, and continues till the opening of the regular session. It is conducted on the same plan as the Spring and Summer Session.

THE REGULAR WINTER SESSION occupies four and a half months—commencing on the third of October, and continuing till the middle of February. The system of instruction embraces a thorough Didactic and Clinical Course, the lectures being illustrated by two clinics each day. One of these daily clinics will be held either in Bellevue or the Charity Hospital. The location of the College building affords the greatest facilities for Hospital Clinics. It is opposite the gate of Bellevue Hospital, on Twenty-sixth street, and in close proximity to the ferry to Charity Hospital on Blackwell's Island, while the Department of Out-door Medical Charity, and the Hospital Post-mortem Rooms, are across the street. The students of the University Medical College will be furnished with admission tickets to these establishments free of charge. The Professors of the practical chairs are connected with one or both of these Hospitals.

Besides the Hospital clinics, there are eight clinics each week in the College building.

The Faculty desire to call attention particularly to the opportunities for dissection. *Subjects are abundant and are furnished free of charge*, and the Professor of Anatomy spends several hours each day in demonstration in the dissecting-room.

FEES FOR THE WINTER COURSE.

Full course of Lectures	$140 00
Matriculation	5 00
Demonstrator's fee, including material for dissection	10 00
Graduation Fee	30 00

FEES FOR THE SPRING, SUMMER, AND AUTUMN COURSE.

Students who have attended the Winter Course will be admitted free of charge. Those who have not attended the Winter Course will be required to pay the Matriculation Fee and $30; and, should they decide to become pupils for the Winter, the $35 thus paid will be deducted from the price of the Winter tickets.

For the purpose of assisting meritorious individuals, the Faculty will receive a few *beneficiaries*, each of whom will be required to pay $48 per annum and the Matriculation Fee.

For further particulars and circulars, address the Registrar,

PROF. HENRY DRAPER, M.D.,
University Medical College,
426 East 26th St., New York City.

CODMAN & SHURTLEFF'S

APPARATUSES FOR

ATOMIZATION OF LIQUIDS

FOR

Inhalation, Local Anaesthesia, &c.

By the Atomizer, any medicated liquid may be converted into the finest spray. In this state it may be inhaled into the smallest air-cells, thus opening a new era in the treatment of all diseases of the throat and lungs.

The Complete Steam Atomizer for Inhalation, &c.

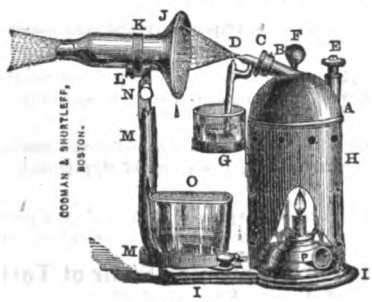

FIG. 15.

THE COMPLETE STEAM ATOMIZER (NEW).

(Patented March 24, 1868, and March 16, 1869.)

All its joints are hard soldered.

It cannot be injured by exhaustion of water, or any attainable pressure, and will last for many years.

It does not throw out spirts of hot water; is convenient, durable, portable, compact, and cheap in the best sense of the word. Can be carried from house to house without removing the Atomizing Tube or the water.

Price, $6.00.

Neatly made, strong, black walnut box, with convenient handle, additional, $2.50.

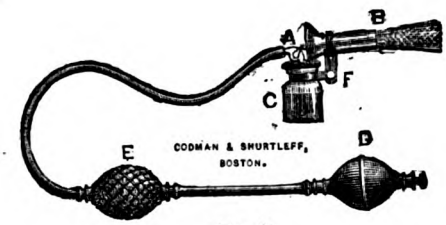

FIG. 5.

SHURTLEFF'S ATOMIZING APPARATUS.

(Patented March 24, 1868.)

The most desirable Hand Apparatus.

Rubber warranted of very best quality. Valves of hard rubber, every one carefully fitted to its seat, and work perfectly in all positions.

Price, $4.50.

The Bulbs are adapted to all the Tubes made by us for Local Anæsthesia in Surgical Operations, Teeth Extraction, and for Inhalation. (For description of Tubes, see pamphlet.)

Each of the above Apparatus is supplied with two carefully made annealed glass Atomizing Tubes, and accompanied with directions for use. The Steam Apparatus is tested with steam at very high pressure. Each Apparatus is carefully packed for transportation, and warranted perfect. Also,

Hand-Ball Apparatus, Fig. 5 (without shield), with two Glass Tubes..... $4 00
Silver-Plated Tubes, for Local Anæsthesia and for Inhalation, each..... 2 00
Rhigolene, for Local Anæsthesia, best quality, packed..... 1 00
Nasal Douche, for treating Diseases of the Nasal Cavity; six different varieties, each with two Nozzles, packed..... $1.20, 1.50, 2.00, 2.50, and 3 50

A PAMPHLET

Containing two articles, by distinguished foreign authority, on "*Inhalation of Atomized Liquids,*" with formulæ of those successfully employed.

Also, an article by Dr. J. L. THUDICHUM, M.R.C.P., on "*A New Mode of Treating Diseases of the Nasal Cavity, with his Formulæ.*"

Also, *an illustrated description of the Best Apparatus for the* above purposes, and for producing Local Anæsthesia by Atomization with Ether, by the method of Dr. RICHARDSON, of London; or with Rhigolene, as described by Dr. HENRY J. BIGELOW, in the "Boston Medical and Surgical Journal" of April 19, 1866, will be sent by mail, post-paid, on application.

A GOLD MEDAL has lately been awarded us by the Middlesex Mechanics' Association, for Atomizing and Surgical Instruments, as will be seen from the following report, signed by a leading New England surgeon and physician:—

"**1503.** CODMAN & SHURTLEFF, Boston, Mass. One Case Surgical Instruments and Atomizers.

"The Committee have no hesitation in awarding for this superb exhibition the highest premium. * * The various other instruments for Inhalation of Atomized Liquids, and for Local Anæsthesia, were all apparently faultless, both in design and workmanship. The exhibitors are regarded as more especially deserving of the highest token of merit for having produced nothing except of their own manufacture. GOLD MEDAL. (Signed) GILMAN KIMBALL, M.D., Chairman."

ALSO, FOR SALE:

(*Descriptive Circulars on Application.*)

Dr. Oliver's Laryngoscopic Lantern..... $4 00
do. do. do. with Auto-Laryngoscopic Attachment..... 5 00
do. do. do. with Auto-Laryngoscopic Attachment, and three Laryngoscopic Mirrors, in case..... 9 00
Dr. H. R. Storer's Combined Speculum..... 6 00
Miller's Intra-Uterine Scarificator, in case, post-paid..... 7 00
Dr. Pinkham's Improved Uterine Scarificator, in case..... 8 00
Dr. Cutter's Retroversion Pessary..... 3 00
do. Simple Prolapsus Pessary..... 3 00
do. Pessary for Flexions..... 3 00
Vaccinators, Automatic, for using crust or lymph fresh from arm, certain, instantaneous, and nearly painless, post-paid..... 3 00
Dr. Knight's Modification of Cammann's Stethoscope..... 9 50

Also, Skeletons, Skulls, Manikins, Anatomical and Pathological Models and Charts on hand, or imported to order; prices on application. A Instruments, Implements, and Materials used by dentists always on hand. Apparatus for Club Feet, Weak Ankles, Bow Legs, Spinal Curvature, and other deformities, made to order.

INSTRUMENTS MADE TO ORDER, SHARPENED, POLISHED, AND REPAIRED.

CODMAN & SHURTLEFF, 13 and 15 Tremont Street, Boston,

MAKERS OF SURGICAL AND DENTAL INSTRUMENTS.

J. MILHAU'S SONS,

PHARMACEUTISTS AND IMPORTERS,

183 BROADWAY, NEW YORK.

FOUNDED BY J. MILHAU, IN 1815.

All prescriptions are Dispensed at this establishment by Graduates of the Colleges of Pharmacy.

The "Original Elixir of Calisaya Bark,"—Trade Mark. Introduced to the profession by J. MILHAU, in 1830. It is a palatable tonic, stomachic, and anti-malarial; useful whenever a pleasant preparation of Peruvian Bark may be required. Dose, one or two tablespoonfuls.

The "Chalybeate Elixir of Calisaya Bark,"—Trade Mark. Is the same, with the addition of four grains Pyrophosphate of iron to the fluid ounce.

The "Golden Cod-Liver Oil,"—Trade Mark. The pure and genuine oil of the U. S. Dispensatory, and unsurpassed by any yet produced.

Etherized "Golden Cod-Liver Oil,"—Trade Mark. This combination is easily borne by those who cannot digest the oil alone. The ether stimulates the pancreas and digestive organs into healthy action, insuring the prompt assimilation of this already singularly assimilable oil.

"Golden Cod-Liver Oil, with the Hypophosphite of Lime,"—Trade Mark. An almond-flavored emulsion of easy digestibility, acceptable to the most fastidious taste of the invalid. Each tablespoonful containing two grains of Hypophosphite of Lime. Dose, a tablespoonful or more.

"Premium Castor-Oil, without Taste or Smell." The literally pure, cold-expressed oil from *freshly picked Castor beans.* It has the full purgative power, without acrid or emetic properties.

Elixir of Quinine; Iron and Bismuth; Elixir of Valerianate of Ammonia; Elixir of Tartrate of Iron and Manganese; Elixir of Pyrophosphate of Iron; Elixir of Calisaya, Iron and Bismuth, &c., &c., in great variety.

Samples and descriptive catalogues, stating composition and doses, furnished to physicians on application.
CHLORAL, PEROXIDE OF HYDROGEN, OZONIZED ETHER, STYPTIC COLLOID, and all the new Preparations.

French Artificial Eyes, Genuine French and German Mineral Spring Waters, and Foreign Remedies of all kinds, of our own importation.

HORSFORD'S ACID PHOSPHATE

(MEDICINAL), PREPARED BY THE

Rumford Chemical Works, of Providence, R. I.,

UNDER THE DIRECTION OF

PROFESSOR E. N. HORSFORD,

Late Rumford Professor at Harvard University, Cambridge, Massachusetts.

The value of preparations of acid phosphates as therapeutic agents is in keeping with well-known chemical principles.

So far as experience goes, Horsford's Acid Phosphate seems to act as if it were nutriment to the cerebral and nervous system, restoring to their normal action secretory organs that have been deranged, giving rigor where there has been debility, and renewed strength where there has been exhaustion.

☞ *It has been found especially serviceable in dyspepsia and disorders incident thereto, in urinary difficulties, proceeding from paralysis of the bladder or sphincter, and is known to be useful in tendencies to gravel and spermatorrhœa, in cerebral and spinal paralysis, mental exhaustion, wakefulness, hysteria, and other nervous affections.*

Each fluid drachm contains:—

·032 of a grain of metallic iron, in the form of oxide combined as an acid phosphate.

1·100 of uncombined, potential tribasic phosphoric acid, mixed with tribasic phosphoric acid, combined as monobasic phosphate of lime, potassa, magnesia, and ammonia.

It contains no pyro-phosphate or meta-phosphate of any base whatever.

Most excellent results have attended its administration for the prostration and nervous symptoms following *Sunstroke.*

Physicians desiring to examine and test this remedy, are requested to apply, by letter or otherwise, to the undersigned.

ALSO,

Horsford's Bread Preparation,

for making light, healthy, and palatable bread, biscuit, cakes, &c., recommended by the highest chemical, physiological, and medical authority in this country and Europe.

201 FULTON STREET, N. Y.

ESTABLISHED 1855.

Kissingen and Vichy Waters, etc.

These popular remedies, as manufactured by

DR. HANBURY SMITH,

are daily growing in favor, in consequence of their

PURITY, FRESHNESS, AND RELIABILITY.

They keep better than the natural; produce precisely the same effects as those do when in their best condition, and are not, like them, variable in composition.

BEWARE OF THE SPURIOUS AND INFERIOR ARTICLES WITH WHICH THE MARKET IS FLOODED.

NEW YORK, March 2d, 1870.

Having carefully examined the improved processes adopted in the laboratory of DR. HANBURY SMITH, and analyzed samples of the MINERAL SPRING WATERS which he offers for sale, I am prepared to testify that the waters are manufactured with the most intelligent and conscientious care, and are every way reliable substitutes for the natural waters. The public estimation in which DR. SMITH'S preparations are held is thus amply justified by my investigations and analyses.

CHARLES A. SEELY,
Late Prof. of Chemistry and Toxicology in the New York Medical College, and of Chemistry and Metallurgy in the New York College of Dentistry.

HANBURY SMITH & HAZARD,
35 Union Square, New York.

MÖLLER'S COD-LIVER OIL

Gained the ONLY FIRST PRIZES at the Great Exhibitions of LONDON, PARIS, Etc.

IT IS NOT SUFFICIENTLY CONSIDERED that the quality of Cod-Liver Oil depends upon the condition of the Fish. The Lofoten Waters, in Norway, are the only known district where the Cod migrate for spawning, and in excellent condition. Hence the well-known superiority of Lofoten Oil; many reject the light brown on account of its unpleasant taste, arising from its being prepared from putrid livers. PETER MOLLER, therefore, by a Special Process, prepares at Lofoten a Pale Oil, distinctly different to the PALE NEWFOUNDLAND, retaining all the curative virtues with a remarkably pure smell and taste.

THE LATE PHYSICIAN to the North London Consumption Hospital, Abbotts Smith, M.D., M.R.C.P., affirms that Möller's Oil is more readily retained by delicate persons, and more efficacious.

THE MEDICAL SOCIETY OF NORWAY has, through its leading members, testified that Möller's Oil is preferred for its beneficial properties.

THE MEDICAL SOCIETY OF NORTHUMBERLAND AND DURHAM pronounced Möller's Oil the best.

PHYSICIANS TO LONDON HOSPITALS, and other eminent men in the Profession, have certified to its superiority.

Dr. L. A. SAYRE, Professor of Orthopedic Surgery in Bellevue Hospital Medical College, New York, says:—"Of late years it has become almost impossible to get any Cod-Liver Oil that patients can digest, owing to the objectionable mode of procuring and preparing the livers. * * * Moller, of Christiania, Norway, prepares an oil which is perfectly pure, and, in every respect, all that can be wished."—Dr. L. A. Sayre, before Academy of Medicine. See MEDICAL RECORD, Dec., 1869, p. 447.

Dr. J. MARION SIMS says:—"For some years I had given up the use of Cod-Liver Oil altogether; but since my attention was called by Dr. Sayre to Möller's Oil, I have prescribed it almost daily, and have every reason to be perfectly satisfied with it."

Sold by Druggists.

HARVARD UNIVERSITY.

Medical Department, Boston, Mass.

SUMMER SESSION....1871.

THE regular Course of Summer Instruction will begin at the Massachusetts Medical College, North Grove Street, Boston, on March 13th, and continue until the next Winter Course of Lectures on the first Wednesday in November. The Session is divided into two Terms by the summer vacation of two months. Gentlemen who finish their undergraduate course during the summer months, should join the Medical School at the beginning of the Fall Term, Sept. 11th; their requisite three years of study being thus completed in time for the special examination for medical degrees, which precedes the annual commencement at Cambridge.

Recitations are held daily by the Professors and Instructors in all the branches necessary to a medical education. Clinical instruction in Medicine and Surgery is also given daily at the Massachusetts General Hospital and the City Hospital. Other Hospitals and the various Dispensaries and Infirmaries in the city are likewise open to students. Lectures on special branches will be given at the College by University Lecturers, and courses on the sciences connected with Medicine. Zoology, Botany, Chemistry, and Physics, will be delivered in Cambridge by the Professors in these departments which students may attend without extra charge.

The CHEMICAL LABORATORY is open during the Summer, and practical instruction is given in physiological, pathological, and toxicological Chemistry. A Laboratory is also opened in which students are thoroughly exercised in the management of the MICROSCOPE.

The DISSECTING ROOM is open and abundantly supplied with RECENT SUBJECTS, during March, April, and October. *No charge is made for anatomical material, or for demonstration.*

FEES.—The fee for instruction during the Summer Session, from March to November, is $100; for the Winter Lectures, $121. The fee for the entire year, for the Winter Lectures as well as the Summer Session, is $200. The fee for Graduation is $30. The fee for Matriculation is $5. This is appropriated to the increase of the Library, and is to be paid to the Dean at once by all who desire to become members of the College.

FACULTY OF MEDICINE.

CHARLES W. ELIOT, LL.D., PRESIDENT.

JOHN B. S. JACKSON, M.D., Shattuck Professor of Morbid Anatomy, and Curator of the Anatomical Museum.
OLIVER WENDELL HOLMES, M.D., Parkman Professor of Anatomy and Physiology.
GEORGE C. SHATTUCK, M.D., Hersey Professor of the Theory and Practice of Physic.
JEFFRIES WYMAN, M.D., Professor of Comparative Anatomy and Physiology.
HENRY J. BIGELOW, M.D., Professor of Surgery and Clinical Surgery.
JOHN BACON, M.D., University Professor of Chemistry.
CHARLES E. BUCKINGHAM, M.D., Professor of Obstetrics and Medical Jurisprudence.
EDWARD H. CLARKE, M.D., Professor of Materia Medica.
CALVIN ELLIS, M.D., Jackson Professor of Clinical Medicine.
RICHARD M. HODGES, M.D., Adjunct Professor of Surgery and Clinical Surgery.
JAMES C. WHITE, M.D., Adjunct Professor of Chemistry, and Lecturer on Diseases of the Skin.
DAVID W. CHEEVER, M.D., Adjunct Professor of Clinical Surgery.
ROBERT T. EDES, M.D., Assistant Professor of Materia Medica.
WILLIAM T. LUSK, M.D., Lecturer on Physiology.

FRANCIS MINOT, M.D., Instructor in Theory and Practice.
JOHN P. REYNOLDS, M.D., Instructor in Obstetrics.
J. NELSON BORLAND, M.D., Instructor in Clinical Medicine.
REGINALD H. FITZ, M.D., Instructor in Pathological Anatomy.
JOHN E. TYLER, M.D., Lecturer on Mental Diseases.
HENRY W. WILLIAMS, M.D., Lecturer on Ophthalmology.
GEORGE DERBY, M.D., Lecturer on Hygiene.
HASKET DERBY, M.D., Lecturer on Ophthalmology.
ROBERT AMORY, M.D., Lecturer on Physiological Action of Drugs.
FREDERIC I. KNIGHT, M.D., Lecturer on Laryngoscopy.
CLARENCE J. BLAKE, M.D., Lecturer on Otology.
CHARLES B. PORTER, M.D., Demonstrator of Anatomy.
HENRY H. A. BEACH, M.D., Ass't Demonstrator of Anatomy.

☞ A detailed account of the Winter and Summer Sessions, as well as of the Harvard Dental School, will be forwarded (post-paid) by DAVID CLAPP & SON, 334 Washington Street, Boston. The Janitor of the College will advise students in the selection of boarding-places, and will always have a list of such as are in the vicinity of the College Building, varying in their rate of charges. Students are invited, on coming to town, to call upon the Dean of the Faculty, 114 Boylston Street, to whom all letters must be addressed.

CALVIN ELLIS, M.D., *Dean of the Faculty.*

Private Instruction in Electro-Therapeutics.

A. D. ROCKWELL, M.D., and GEO. M. BEARD, M.D., are prepared to give private instruction in Electro-Therapeutics to Physicians and Students of Medicine, either singly or in classes.

Plan of Instruction.—Electro-Physics and Electro-Physiology in their practical bearings on Electro-Therapeutics, Electro-Diagnosis, Electro-Physiological and Electro-Therapeutical Anatomy. General and Localized Electrization, with both Faradic and Galvanic Currents, with special reference to the Diagnosis and Treatment of Diseases of the Nervous System. Electro-Surgery, including Electrolysis and Galvano-Cautery.

The course will be thoroughly practical, including demonstration on both Medical and Surgical cases.

For particulars, address Dr. BEARD or Dr. ROCKWELL, 40 East 30th street.

ELEMENTARY TREATISE

ON

PHYSICS,

EXPERIMENTAL AND APPLIED, FOR THE USE OF COLLEGES AND SCHOOLS.

Translated and Edited from GANOT'S ÉLÉMENTS DE PHYSIQUE.

BY E. ATKINSON, PH.D., T.C.S.

Fourth Edition, Revised and Enlarged by the addition of over 40 pages of matter. Profusely illustrated, in one thick 8vo vol. Price, $5.00.

WM. WOOD & CO., Publishers,
NEW YORK.

DETROIT MEDICAL COLLEGE.

The Third Annual Session of this Institution will open on March 2d, 1871. There will be a Preliminary Term beginning on January 3d, and continuing until the opening of the Regular Term. Fees for both Terms are:

Matriculation Fee	$ 5 00
Hospital Tickets	6 00
Lecture Fees	50 00
Graduation Fee	25 00

For further particulars and circulars, address
E. W. JENKS, M.D., President of Faculty, 92 Fort Street West.
Or, THEO. A. McGRAW, M.D., Secretary, 545 Jefferson Avenue, Detroit, Mich.

Sent Free by Mail on Receipt of Price.

A Handbook of Hospital Practice;

or, an Introduction to the Practical Study of Medicine at the Bedside. By ROBERT D. LYONS, M.D., K.C.C., etc., etc. 2d edition. In one handy 12mo volume of 238 pages, bound in muslin, $1.25.

WM. WOOD & CO., Publishers, 61 Walker St., N. Y.

STRONG DRINK AND TOBACCO SMOKE:

THE STRUCTURE, GROWTH, AND USES OF

MALT, HOPS, YEAST, AND TOBACCO.

One Hundred and Sixty-seven Illustrations, Drawn and Engraved on Steel.

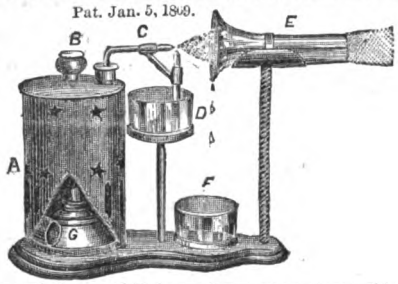
Opposite Park Street Church,

BOSTON, MASS.

Leach & Greene's Improved Steam Atomizer.

Pat. Jan. 5, 1869.



We have entirely remodelled our former apparatus, making several important improvements, and we now offer it to the profession as the cheapest, most durable and efficient apparatus in use. Every part is constructed with the utmost care from the best materials, and is tested by us personally. Leach's Improvement in Atomizing Tubes, for which a patent has been granted, possesses decided advantages over any in use. This Improvement secures the glass tube from movement in the flexible metal connections, which allow adjustment of the points, and render them less likely to break.

Price of Improved Steam Atomizer, complete, $4.00.

The Spray Producer; or, Instrument for Local Anæsthesia.

A modification of Richardson's original instrument, applicable for freezing, with Ether or Rhigolene, or for inhalation in diseases of the Throat or Lungs. Price of Apparatus, with extra glass Bergson Tube, $5.

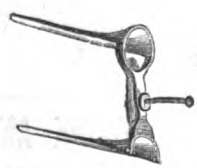
The Boston Speculum.

Dr. H. R. Storer's modification of Cusco's Speculum, combining two instruments in one. Price, $6.00.

FIG. 1.

Representing the instrument when used as the ordinary Cusco's Speculum.

FIG. 2.



Representing the instrument when used as a Sims' Retractor.

Prof. Loomis' Ovum and Bullet Forceps.

A very useful instrument in cases of Uterine Hemorrhage for removing the ovum or placenta.

FIG. 1

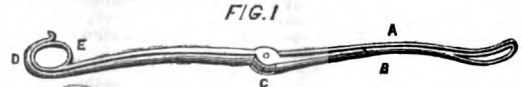


FIG. 2

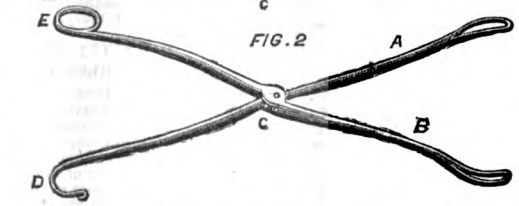

Fig. 1 represents the instrument closed, in which position it can easily be passed into the uterus, as the blades are only half an inch in width and a third in thickness. Fig. 2 represents the instrument opened; the blade A can be rotated as well as opened at the joint C, and after introduction may be slightly opened and swept around in contact with the lining membrane of the uterus, enabling the operator to detach the placenta or ovum, and grasp it firmly, so that it may be withdrawn with the instrument. Price $7.00.

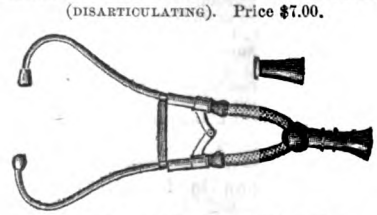
Cammann's Improved Double Stethoscope.

(DISARTICULATING). Price $7.00.



Thudichum's Nasal Douche,

Or, APPARATUS FOR TREATING DISEASES OF THE NASAL CAVITY.

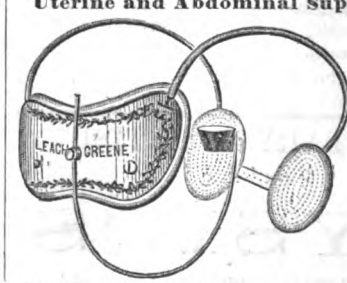
Packed in box, with two nozzles. Price, $2.00.

Thudichum's Nasal Speculum,

FOR EXAMINATION OF THE ANTERIOR NARES.

The long valve expands the ala, the short rests upon the septum, giving a very perfect view of the nasal cavity. A right and left Speculum are required. Price per set, $1.50.

Uterine and Abdominal Supporter Combined.



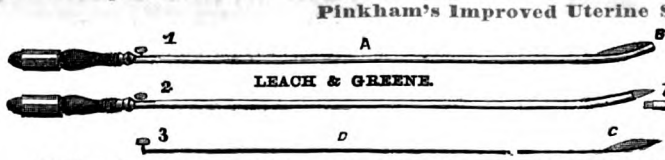
A most effectual apparatus for the relief of

PROLAPSUS UTERI.

The cup is of Hard Rubber, supported by a flexible wire, electroplated with gold, is free from liability to corrosion, will not irritate, can be moulded to fit the form of the Pelvis.

Price, $10.00.

Pinkham's Improved Uterine Scarificator.



The advantages of this instrument are that it can be used for puncturing and scarifying the margins of the os externum, as well as for scarifying the interior of the uterus. It is easily cleansed; it is firmer and less liable to get out of order than the other forms.

Price, $6.00; in case, $7.00.

A full assortment of Surgical Instruments of the best quality and finish always in Stock. The latest improvements and new inventions promptly added.

Laryngoscopes, complete, $14 to $16; Simple Throat Mirrors, $1 to $1.25; Cutter's Pessaries for Retroversion, Prolapsus, and Flexions, each, $3; Barnes' Dilators, set of three with Stop-cocks and Inflator, $7; Carbolized Sponge Tents, coated with Cocoa Butter, per dozen, $3; Hypodermic Syringes, $3 to $5; Bowman's Probes, per set, $3; Williams' Modification of same, per set, $3; Surgeons' Pocket Cases, $10 to $36; Amputating Cases, $30 to $32; Compound Operating Cases, $45 to $200.

Descriptive Circulars furnished on application. Having secured the services of experienced English weavers, we are prepared to make to measure every variety of Elastic Hose or Bandage.

BELLEVUE HOSPITAL MEDICAL COLLEGE,

CITY OF NEW YORK.

SESSIONS OF 1870-71.

THE COLLEGIATE YEAR in this Institution embraces a Preliminary Autumnal Term, the Regular Winter Session, and a Summer Session.

THE PRELIMINARY AUTUMNAL TERM for 1870-71 will commence on Wednesday, September 14, 1870, and continue until the opening of the Regular Session. During this term, instruction, consisting of didactic lectures on special subjects, and daily clinical lectures, will be given, as heretofore, exclusively by members of the Faculty. Students designing to attend the Regular Session are strongly recommended to attend during the Preliminary Term, but attendance during the latter is not required. During the Preliminary Term clinical and didactic lectures will be given in the same number and order as in the Regular Session.

THE REGULAR SESSION will commence on Wednesday, October 12th, and end about the 1st of March, 1871.

FACULTY.

ISAAC E. TAYLOR, M.D., Emeritus Professor of Obstetrics and Diseases of Women and Children, and President of the College.
JAMES R. WOOD, M.D., LL.D., Emeritus Professor of Surgery.
FORDYCE BARKER, M.D., Professor of Clinical Midwifery and Diseases of Women.
FRANK H. HAMILTON, M.D., LL.D., Professor of Practice of Surgery with Operations, and Clinical Surgery.
LEWIS A. SAYRE, M.D., Professor of Orthopædic Surgery and Clinical Surgery.
ALEXANDER B. MOTT, M.D., Professor of Surgical Anatomy with Operations, and Clinical Surgery.
W. H. VAN BUREN, M.D., Prof. of Principles of Surgery with Diseases of the Genito-Urinary System, and Clinical Surgery.
BENJAMIN W. McCREADY, M.D., Professor of Materia Medica and Therapeutics, and Clinical Medicine.
GEORGE T. ELLIOT, M.D., Professor of Obstetrics and the Diseases of Women and Children, and Clinical Midwifery.
STEPHEN SMITH, M.D., Professor of Descriptive and Comparative Anatomy, and Clinical Surgery.
AUSTIN FLINT, M.D., Professor of Principles and Practice of Medicine, and Clinical Medicine.
R. OGDEN DOREMUS, M.D., Professor of Chemistry and Toxicology.
WILLIAM A. HAMMOND, M.D., Professor of Diseases of the Mind and Nervous System, and Clinical Medicine.
AUSTIN FLINT, JR., M.D., Professor of Physiology and Microscopy, and Secretary of the Faculty.

SPECIAL LECTURES IN THE REGULAR TERM.

OPHTHALMOLOGY—By Prof. HENRY D. NOYES, M.D.

DISEASES OF THE SKIN—By Prof. FOSTER SWIFT, M.D.

A distinctive feature of the method of instruction in this College is the union of clinical and didactic teaching. All the lectures are given within the Hospital grounds. During the Regular Winter Session, in addition to four didactic lectures on every week-day, except Saturday, two or three hours are daily allotted to clinical instruction. The union of clinical and didactic teaching will also be carried out in the Summer Session, nearly all of the teachers in this Faculty being physicians and surgeons in the Bellevue Hospital and the great Charity Hospital on Blackwell's Island.

The Session will consist of two Recitation Terms; the first from March 14th to July 1st, and the second from September 1st to the opening of the Regular Session. During this Session there will be daily recitations in all the Departments held by members of the regular Faculty and their assistants. Regular clinics will also be held daily.

FEES FOR THE REGULAR SESSION.

Fees for tickets to all the lectures during the Preliminary and Regular Term, including clinical lectures	$140 00
Matriculation fee	5 00
Demonstrator's ticket (including material for dissection)	10 00
Graduation fee	30 00

FEES FOR THE SUMMER SESSION.

Matriculation (Ticket good for the following Winter)	$5 00
Recitations and Clinics	35 00
Chemical Laboratory (including material)	25 00
Dissecting (Ticket good for the following Winter)	10 00

Graduates of the Bellevue Hospital Medical College, and students who have attended two full Winter Courses at the College, will be admitted to the lectures of the Winter and Summer Session on the Matriculation ticket; all others will be required to take out tickets.

Payment of Fees is invariably required at the commencement of the Session. There are no exceptions to this rule.

Students, on arriving in the city, are requested to report at once at Bellevue Hospital, situated on the East River, between Twenty-sixth and Twenty-eighth Streets, and inquire for the Janitor of the College, who will take pains to aid them in securing comfortable accommodations without delay. The Entrance to the Hospital is on Twenty-sixth Street.
